The report spoke of the increase in the routine office work during the year and pointed out that the clerical work required by the officers and various committees of the Society had demanded more and more of the time of the office staff. To Miss Davies and her assistants the report gave unstinted praise for the handling of the work.

Dr. Smith moved the adoption of this report. The motion was seconded by a councilor.

Dr. Lee commented on the excellence of the report and said that with its adoption should go the grateful thanks of the Council. This motion was adopted by vote of the Council.

Committee on Arrangements — Dr. Gordon M. Morrison, Middlesex South, chairman.

Dr. Roy J. Heffernan, Norfolk, a member of the committee, announced, in Dr. Morrison's absence, that the committee had no report.

Committee on Ethics and Discipline — Dr. Ralph R. Stratton, Middlesex East, chairman.

No report.

Committee on Medical Education — Dr. Robert T. Monroe, Norfolk, chairman.

No report.

Committee on Membership — Dr. Harlan F. Newton, Suffolk, chairman.

No report.

Committee on Public Health — Dr. Francis P. Denny, Norfolk, chairman.

No report.

Committee on Medical Defense — Dr. Arthur W. Allen, Suffolk, chairman.

No report.

Committee on Society Headquarters — Dr. William H. Robey, Suffolk, chairman.

No report.

Committee on Finance — Dr. Francis C. Hall, Suffolk, chairman.

Dr. Hall called the councilors' attention to the committee's report (Appendix No. 5) as printed in the advance sheets of information beginning on page 3.

Dr. Hall moved the acceptance of the report. This was seconded by a councilor, and it was so ordered by vote of the Council.

Dr. Hall moved the adoption of the budget for 1944. This motion was seconded by a councilor.

Dr. Lester M. Felton, Worcester, spoke of a communication that he believed Dr. Brainard F. Conley had sent to Dr. Hall. Dr. Hall expressed his thanks to Dr. Felton for this reminder. The letter, Dr. Hall said, was to the effect that, whereas the Committee on Legislation had asked for \$100 originally, it was apparent that, because of national legislative matters, the committee would need a total of \$2000.

Dr. Hall moved, as an amendment to his original motion to adopt the budget as recorded in the advance sheets, that the sum of \$1900 be added to that which had been allowed the Committee on Legislation. This amendment was seconded by Dr. Felton.

Dr. George Leonard Schadt, Hampden, asked if the duties of the Committee on Legislation concerned this committee with national legislative matters. He was answered in the affirmative by the chair, who read Section 4 of Chapter VII of the by-laws. The motion as amended was adopted by vote of the Council.

Committee on Industrial Health — Dr. Dwight O'Hara, Middlesex South, chairman.

No report.

Massachusetts Committee on Procurement and Assignment — Dr. Reginald Fitz, chairman.

This report was offered as a courtesy to the Massachusetts Medical Society.

The report (Appendix No. 6), which was read by Dr. Fitz, stated that half the members of the Society less than forty-five years of age and two thirds of the members thirty-eight years old and younger were in active military service and that it was difficult to perceive how many more practicing physicians could be withdrawn without resulting in serious difficulty in the matter of the medical care of the civilian population.

The report spoke of the decision of the Surgeon General to no longer recommend the commissioning in the medical corps of graduates of a certain school and said that many of the young men affected by this decision were continuing to serve as residents and interns in hospitals badly needing them and that others had opened offices in areas claiming to need physicians. The report added that few, if any, had been drafted by Selective Service as privates.

The report spoke of the 9-9-9 plan for interns and residents.

Having in mind the influenza epidemic of twenty-five years ago, the report spoke of plans that were being jointly worked out with the War Participation Committee of the Massachusetts Medical Society, by which a type of emergency service could be established in the Commonwealth.

Dr. Fitz moved the acceptance of the report. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Committee on Public Relations — Dr. Albert A. Hornor, Suffolk, secretary.

Dr. Hornor reported as follows:

The committee met on December 15, 1943, at the Harvard Club and in addition to the president, president-elect, vice-president and secretary of the Society, there were representatives of twelve district societies.

The minutes of the last meeting were approved as distributed to members of the committee.

The report of the committee invited to sit with the Advisory Council of the Committee on Unemployment and Social Security for the Commonwealth of Massachusetts was presented as a progress report and discussed by all members present. It was duly moved and seconded and finally passed by unanimous vote that the Committee on Public Relations endorse and continue study, by subcommittee, of plans for sickness and indemnity insurance as presented before the above-named committee.

A progress report was received from the subcommittee to look into the possibility of better publicity for the Massachusetts Medical Society. The Committee on Public Relations voted unanimously in favor of a study for means of public education regarding the Massachusetts Medical Society by its subcommittee on publicity.

The Committee on Public Relations was designated, by President Lee, as the committee of the Society to function with the Council on Medical Service and Public Relations of the American Medical Association.

The formulary of drugs for recipients of public welfare, as published by the Department of Public Welfare, was discussed and referred to the Subcommittee on Tax-Supported Medical Care for study and appropriate report.

Dr. Hornor moved the acceptance of the report. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Subcommittee to Meet With the Medical Advisory Committee of the Industrial Accident Board —

Dr. Daniel J. Ellison, Middlesex North, chairman.

No report.

Subcommittee on Tax-Supported Medical Care —

Dr. Elmer S. Bagnall, Essex North, chairman.

Dr. Bagnall reported as follows:

To this subcommittee of the Committee on Public Relations was referred the matter of the *Formulary* at the first meeting of the Committee on Public Relations. Our report has not had a chance to be reviewed by the Committee on Public Relations and unless the Council desires otherwise, we think that it should wait until the Committee on Public Relations receives it.

Dr. Lee announced that Dr. Bagnall's report was accepted as a report of progress.

Subcommittee on Postpayment Medical Care (Bank Plan) — Dr. Elmer S. Bagnall, Essex North, chairman.

No report.

Subcommittee Concerned With Prepayment Medical-Care Costs Insurance — Dr. James C. McCann, Worcester, chairman.

Dr. McCann reported as follows:

I shall make a brief statement with respect to the present status of the corporation. At the last meeting of the Council we anticipated an enrollment of 15,000 subscribers by the first of the year. Today, the enrollment is 25,000, which is probably the most satisfactory response under the restricted program we offer — surgical-obstetrical benefits — that has been experienced by any of the states except Michigan, which has always had a most unusual experience.

Regarding the financial condition of the corporation, as we had anticipated in the last report, all the organizational expenses and current expenses have been taken care of, and we are operating in the black, and it looks as if during the next year a satisfactory surplus will begin to appear on the books. This is in addition to a rather rigid requirement of placing aside a reserve of 25 per cent, as required by the Commissioner of Insurance.

With reference to the accumulation of reserves, the Board of Directors has already begun to discuss an extension of the basic contract to include medical care in the hospital. This, of course, would be much to our advantage in any new program. The control of this matter is also in the hands of the Department of Insurance in so far as they will require a satisfactory financial condition before we make this extension. In conversation with the deputies in the office of the Department of Insurance, they agreed to review our rates as of June and to make recommendations to us, and also to examine any plan that we may suggest for extending the benefits.

The relations of the corporation with the profession have so far been eminently satisfactory. In the office we are quite conscious of the delay in the handling of the reports from the profession and in making the final settlement of accounts; but this is an unavoidable situation until the administrative forces in the office become acquainted with the entirely new matter of medical problems as compared with the usual hospital problems. All along the way steps are being taken to eliminate such problems as delay in the handling of accounts, and I think that during the next year the members of the profession will find that matters will be handled in an increasingly satisfactory manner — at least that is our hope.

This is just an informal report, and I move that it be accepted as such.

Dr. McCann's report was accepted as a report of progress.

Committee on Legislation — Dr. Brainard F. Conley, Middlesex South, chairman.

The report, which was offered by Dr. Lester M. Felton, Worcester, is as follows:

Since the last meeting of the Council there have been four meetings of the Executive Committee. The executive group of five members and one meeting of the latter group with the Legislative Committee of the Massachusetts State Pharmaceutical Association.

There has been established full, active co-operation between the druggists and the physicians of Massachusetts on matters of legislative interest to both professions.

The Massachusetts State Pharmaceutical Association has issued, at no small expense, a great amount of literature to the public through the drugstores of the State. This particular literature has to do with the dangerous aspects of the pending Wagner-Murray-Dingell Bill. On February 9 this association of druggists will hold its midwinter convention in Worcester. A portion of that afternoon will be given over to the Massachusetts Medical Society. Dr. Roger I. Lee, Dr. James C. McCann and the chairman of the Committee on Legislation have accepted invitations to speak during that period. The pharmaceutical profession of Massachusetts is bitterly opposed to the passage of the Wagner-Murray-Dingell Bill. As individuals, the druggists are doing more for the

doctor than the latter is doing for himself. Collectively, through committees, both professions are equally active.

The Committee on Legislation has given careful study to the part of the Wagner-Murray-Dingell Bill that pertains to the practice of medicine. We are convinced that passage of this legislation would bring about a regimentation of the American people into a federal system of socialized medicine and compulsory governmental hospitalization and bring about a dangerous revolution, which would be detrimental to health care. Plans are under way for a state-wide campaign in opposition to this pending legislation. The progress of this menacing threat to proper medical care for the American people is being watched each day by the members of this committee.

The committee believes, from conversations with many members of the Society, that it would be of advantage in many ways if a section of the *New England Journal of Medicine* could be devoted to medical economics. Such a section would, we believe, be welcomed by a majority. Most economic changes have or will come through legislation. Therefore this committee makes the suggestion.

Dr. Felton moved the acceptance of this report. This motion was seconded by a councilor.

Dr. Hyman Morrison, Norfolk, said that he thought the apparently unanimous opinion on the Wagner-Murray-Dingell Bill cannot be a true expression of what people are really thinking about it. He added: "Can it be such a terrible proposition that the unanimous opinion of the medical profession is against it. It is very gratifying to read the statement of the Massachusetts Medical Society in co-operation with the other state medical societies of New England."

Dr. Lee ruled that the Wagner-Murray-Dingell Bill was not under discussion at that time and that opportunity would be had for such discussion later in the meeting.

The report of the Committee on Legislation was accepted by vote of the Council.

Dr. Felton moved that the Committee on Legislation meet with the Committee on Publications to the end of devising methods of education in medical economics. This motion was seconded, and it was so ordered by vote of the Council.

Committee Appointed to Consult With Representatives of the other New England State Medical Societies Regarding the Wagner-Murray-Dingell Bills — Dr. Walter G. Phippen, Essex South, chairman.

This report (Appendix No. 7) was offered by Dr. Phippen. He referred the councilors to pages 1, 2 and 3 of the advance sheets of information for the full text of the report.

Dr. Phippen moved the acceptance of the report. This motion was seconded by a councilor and it was so ordered by vote of the Council.

Dr. Phippen moved that the Council approve the action of the Executive Committee in approving this report and authorizing the release of the following letter:

MASSACHUSETTS MEDICAL SOCIETY
6 Fenway, Boston

December 2, 1943

Dear Sir:

The Massachusetts Medical Society, in conjunction with the medical societies of Maine, New Hampshire, Vermont, Rhode Island and Connecticut, has studied Senate Bill 1161 and House Bill 2861 now before the

Congress of the United States and respectfully submits its views on this proposed legislation.

We approve of the broad medical objective of the act that we interpret to be an attempt to improve the health of the people. As a basis of our approval we cite the progressive leadership which the physicians of New England have always shown in the development of public-health enterprises. For more than fifty years we have consistently supported the plea for the establishment of a National Department of Health with a secretary in the President's Cabinet, under whom would be co-ordinated many important public-health programs, exclusive of the Army and Navy. These are now scattered through various departments and bureaus of the federal government and already play a large role in the provision of medical care for the people of this country.

We approve of the use of the insurance principle on a voluntary basis as a means to aid the individual to budget against the cost of medical care. We maintain that when insurance programs are not directly under the supervision of the medical profession by whom medical care is to be rendered, they should provide for cash benefits to be paid to the individual, for we firmly believe that the citizens of New England are capable of using cash benefits to pay the costs of medical care.

We believe that S. B. 1161 and H. B. 2861 do not provide for the sound development of a national health program. It is implied by the act that the distribution of compulsory savings managed by federal authorities will guarantee better health for all the people. We sincerely doubt that such objective can be realized in this way. In the New England states, judged by any standards with which we are familiar, there is no need to revolutionize the habits of the people in their methods of obtaining medical care.

Private enterprises in the field of voluntary prepaid medical and hospital insurance are increasing rapidly. *These facilities should be utilized by the states, if necessary through federal grants-in-aid, so that each state can purchase medical care for those who cannot purchase it for themselves.* This we believe to be a development that would be acceptable to the New England people, for thereby medical care could be provided even for the indigent who are public charges, a provision most desirable in those communities that have been unable or unwilling to meet this obvious responsibility.

We shall be glad to work out plans with representatives of the federal and state governments to improve the health of all the people, but we should expect that any plans that might be devised would take full advantage of existing agencies and be developed with the social patterns that are well understood by our people.

Very truly yours,

[Signed] Roger I. Lee
ROGER I. LEE, M.D., *President*
[Signed] Michael A. Tighe
MICHAEL A. TIGHE, M.D., *Secretary*

This motion was seconded by a councilor.

Dr. Hyman Morrison was recognized by the chair. He spoke as follows:

I want to apologize again that, in my zeal to bring up the discussion on the Wagner-Murray-Dingell Bill, I ran ahead of the program.

But it seems to me, I repeat, that a measure of such importance surely cannot but meet two points of view. As intelligent men we cannot accept a measure of such wide implication without giving it great thought and without feeling that there are two sides to the question. Few have read the bill: it covers over sixty pages. I admit I have not read it, but I did hear Senator Murray speak on it. If we have not thought about it or heard what the bill means to do, then unanimous acceptance or disapproval of it does no credit to any body of men.

It is gratifying that the medical societies of the New England states have met with great self-restraint the proposition now pending before Congress. A great stride forward has been taken when organized medicine began to approve voluntary medical insurance. That in itself indicates great progress in the thinking of our profession. It is not so long ago that any effort at prepayment medical service was considered taboo, and I think Dr. McCann will support me in this with his experience in the organization of the Massachusetts Medical Service. If nothing else, the health measures before Congress during the past decade have surely challenged the medical profession and have stimulated us to plan more adequate service for the low-income groups of the population.

The great objective of the bill is to give adequate medical care to the millions of people in America who do not get it. This may not apply to Massachusetts or Vermont, but nevertheless there are millions of people who cannot obtain good medical service without pauperizing themselves, as they do in the free clinics. This goes against the grain of human dignity. What the legislation under discussion proposes, in a broad way, is to make it possible for people with low incomes to get adequate medical care without pauperizing themselves—through compulsory insurance. This seems to me a great advance. It does not intend to do away with private practice; nor should it disturb the traditional cordial relation between physician and patient.

Why should it be different to the physician, worthy of the name, whether he is paid by the individual or through a collective fund?

It has been said that this sort of legislation is an infringement on our freedom as individuals. Now it seems to me that we take an attitude toward our government as if it were something foreign, coming in from the outside and infringing on our rights. Do we forget that the Government is what we make it? Our Congressmen are elected. The Government is the American people, responding to the will of the majority.

So I appeal, not particularly for this measure, but for a dignified attitude toward this type of legislation, and I am grateful as an individual to the officers of the New England medical societies for the broad aspect they have taken toward the bill.

It was suggested by Dr. J. Harper Blaisdell, Middlesex East, that when the vote on this question was taken it be by a show of hands. This suggestion met with the approval of the Council.

Dr. Schadt asked how it was that this letter was adopted before being submitted to the Council. Dr. Lee replied that it was published under authorization of the Executive Committee of the Council.

In response to the same question and on the invitation of the chair, Dr. Phippen spoke as follows:

We had several meetings and conferences with the members of the other state societies. They were very good to come and spend long afternoons with us in the Boston Medical Library. We usually spent three hours at a session, and we discussed almost every aspect of the Wagner-Murray-Dingell Bills. Dr. Morrison says he has not read the bill, and I venture to say that if we took a poll of this group here we should find that few of you have read the bill completely, and I cannot say that I blame you very much. It is very tiring and wearisome reading.

You asked us to study the bill and make some statement that would cover the consensus of a majority of the medical men. Now we do not say that these words that we have set down in print are the words that each one of you would have chosen if you were doing the same job that we had to do; but we believe, by and large, that they fairly represent the general opinion of medical men all over New England. At the second session we agreed to go our ways for a spell and to talk with all our neighbors and friends in order to ascertain how they felt about the bill. When we met again this letter was the result of the consensus. The other societies were anxious to get this into the hands of all the senators and representatives as soon as possible; and, since a meeting of the Council was not scheduled until today, we asked the Executive Committee if they would authorize us to go ahead and join with these other societies in releasing this statement, which the Executive Committee did.

The motion to approve the action of the Executive Committee of the Council was adopted, the vote being 176 for and 3 against.

Committee on Cancer — Dr. Ernest L. Hunt, Worcester, chairman.

Dr. Hunt announced that the full text of the report (Appendix No. 8) had appeared in the advance sheets of information beginning on page 9. He said that the report concerned itself with certain new regulations that had been set up by the Massachusetts Department of Public Health for the regulation of the state-aided cancer clinics. He added that the Committee on Cancer was not in accord regarding its recommendations anent these new regulations and that, therefore, a majority and a minority report

were submitted. He noted the absence of Dr Daland's name from the majority report. He explained that, although Dr Daland was not present at the last meeting of the committee, he did vote with the majority at an earlier meeting.

He added that the majority of the committee recommended that the Council take no action on these recommendations pending a six months' trial and that the minority recommended that the new regulations be not approved by the Council in so far as they relate to the collection of fees to be applied to the expense of conducting the clinics.

Dr John M. Fallon, Worcester, moved the acceptance of the report. This motion was seconded by a counselor, and it was so ordered by vote of the Council.

Dr Lee explained that Dr Hunt, not being a member of the Council, could not participate in the debate on this subject without the unanimous consent of the Council.

Dr David Cheever, Suffolk, moved that this consent be given. This motion was seconded by a counselor, and it was so ordered by vote of the Council.

Dr Frederick S. Hopkins, Hampden, moved the adoption of the majority report. This motion was seconded by a counselor.

Dr Felton asked the chair if this meant that one could ignore for six months anything that the Department of Public Health had to say regarding this. Dr Lee replied that he thought it meant that there would be no action by the Council during that time.

Dr Philemon E. Truesdale, Bristol South, said that he was one of those who voted in the committee to recommend deferment of action by the Council for six months. He added that the ruling put out by the Attorney General was, after all, the opinion of one lawyer and that, until its correctness was established by the courts, it could not be said to be constitutional. He referred to the survey of the state-aided cancer clinics recently made by Dr Channing Simmons and to its conclusion that sixteen clinics were doing excellent work and that in seven this work was substandard. He also spoke in a complimentary manner of the Fall River Clinic, under the chairmanship of Dr Thomas Almy, and said that these clinics are doing a work of charity for the common good. He thought that it might be wise to refer this matter to the attorneys of the Society for their interpretation.

Dr Charles C. Lund, Suffolk, in favoring the adoption of the majority report, said that the Department of Public Health was bound to follow the Attorney General's recommendation and that, as a consequence, this department had to set up certain new regulations. He added that the state-aided cancer clinics had been operating under these new regulations for two months. He spoke of a conversation that he had with Dr Lombard, during

the course of which he had been informed that, for this two-month period, a total of about \$69 had been collected under these new regulations and that this represented a little over \$2 per clinic per month.

Dr Bernard Appel, Essex South, in speaking in opposition to the adoption of the majority report, said that he was the dermatological consultant to the Lynn Cancer Clinic and that he looked up some figures which showed that between 50 and 60 per cent of the cases that are seen at this particular clinic are skin cases. He spoke of a woman who saw him at a skin clinic for 50 cents, she was then referred to the cancer clinic and saw him there for \$10. His conclusion was that there was something wrong with such a situation. "We say," he continued, "Let us charge them \$10 because that is the law, but we do not expect anybody to pay it—in other words, do not pay any attention to it."

Dr Phippen spoke as follows:

"This cancer business seems to be quite a question and I think the fact is that the Attorney General has rendered a definite report that the Commissioner of Health is bound to follow, but for us today to accept the minority report and thereby upset the machinery that the Commissioner of Health has set up seems very unwise. The \$10 fee in the cancer clinic is ridiculous and something has got to be done about it. There is not much sense in charging such a fee and then saying to the patient 'Well you don't have to pay \$10. You can pay 50 cents and it will be all right.' But I think we should accept the majority report with the understanding that the Committee on Cancer get busy with the Commissioner of Health to straighten the thing out. I am sure it is quite possible for him to come to some definite arrangement that is agreeable to the committee and to the Council. I am in favor of allowing them six months of grace to get busy and do something about it."

Dr Fallon said that he might have oversimplified this matter in his own mind, but that it looked to him as if the question was whether or not a person able to pay \$10 belonged in a state clinic.

Dr George A. Moore, Plymouth, emphasized the fact that the cancer clinics are diagnostic and that he would like very much to have these new regulations tried out for six months.

Dr Hunt was then invited by Dr Lee to enter the discussion. He spoke as follows:

"I am sure that the diffused opinions we have just listened to show that there is some need of light in this picture—making statements that seem to be much beside the point of the matter. I might refer to Dr Lund's contention that it is too small to take any notice of by reminding you of the mother who thought that her unmarried daughter's illegitimate baby ought to be overlooked because it was so small. If I should use the cancer nomenclature I would say that this is just a little pimple. Compared with the Wagner Bill it is quite tiny—but it is just as important in its principle."

"As chairman of the Committee on Cancer I venture to present a minority report at variance with that of the majority because of my conviction supported by the opinion of the Worcester Cancer Clinic Committee of which I am also chairman that the implications of certain features of the new rules and regulations are such as may embarrass those members of the Society who staff the clinics in the esteem of their fellows. Consequently the enlightened opinion of the Council is sought for their guidance and for its influence on the policies of the State Department of Public Health."

In other words, it is a matter involving the question whether it is right or wrong, whether it is ethical and proper or not. But the thing they have not mentioned is that, whereas a fee of \$10 is the upper limit, they do not exclude anybody. Any millionaire can walk in and get that service for \$10, and that is where it reflects against the medical profession.

The objectionable features are found in those clauses which relate to the collection of fees for clinic services and the use of the funds realized from such fees.

It is contended that the plan (1) extends state medicine beyond the intent of the Constitution, (2) exploits the voluntary services of the clinic staffs to reduce the cost of the clinics to the State, (3) puts the clinics into unfair competition with private consultants, including their own staff members and (4) puts an unfair burden of legal responsibility on the unpaid members of this society who head the local clinics. Let us examine these contentions in more detail:

(1) *The new plan extends state medicine beyond the intent of the Constitution.* So long as a state agency offers to sell, under whatever guise, medical services to persons outside the indigent and near indigent classes, at rates equivalent to those accepted by local custom for private sources of the same services, it is invading the field of free medical enterprise. It thereby violates the spirit of the constitution and good public policy. It cannot, in fairness, require practitioners of medicine to comply with its own educational and quality of service standards through license to practice and then undermine their field in order to ease its own financial commitments whenever it decrees it expedient to do so.

Heretofore the clinics have been a co-operative effort between the Department of Public Health, the physicians and the hospitals. Because of the universality of the cancer problem and the supposed taxpayers' rights no limitation has been placed on who should be received for consultation and diagnosis in the clinics. Since no fees were charged and no financial gain accrued to either member of the co-operative group, no one found fault until the Attorney General discovered that, in serving persons able to pay, the Department of Public Health, through the clinics, was violating the Constitution. So the Department devised this new plan, and in order to "as far as possible maintain the former status of the clinics" (quoted from letter of Dr. Getting of January 21, 1944) put them on a pay basis for persons above the indigent level and fixed a fee of \$10 or fraction thereof. Such a fee is equivalent to private consultation fees in many parts of the state.

(2) *Exploits the voluntary services of the clinic staffs to reduce the cost of the clinic to the State.* The rules provide that even though fees of \$10 are to be charged those patients able to pay, the services of hospital and medical staff remain on a gratuitous, contributory basis.

Who gets the money? At the end of the month all receipts from fees are deducted from the bill sent the State for the expenses of the clinic; therefore, the state gets it. Thus medical charity is extended beyond the needy patient to the treasury of the Commonwealth. The remedy is to give up the pay clinics or to pay doctors and hospitals.

(3) *Puts the clinics into unfair competition with private consultants.* The rules provide no authority whereby any citizen, however opulent, may be excluded from the benefits of the clinics. On the other hand, they offer him a bargain for they require the presence of a surgeon, a pathologist and a radiologist at each clinic so that the patient shall have the benefit of so-called "group diagnosis." When the average purchaser can get the services of three clinic experts for the price of one private expert, which will he be likely to choose?

A feeble attempt to prevent this exploitation is found in the foreword to the rules and regulations, wherein the referring doctor is permitted to provide the clinic with information in regard to the patient's ability to pay, but whether he does or not the clinic has no authority to exclude the patient and is obligated to collect fees from him if the doctor says he is able to pay.

The referral card that doctors are supposed to use, but seldom do, suggests to the doctor that he decide what persons are eligible to clinic services but does not make the patient's admission conditional on his doing so. If he does give any information the clinic must take his word for it.

(4) *Puts an unfair burden of legal responsibility on the unpaid members of this society who head the local clinics.* To save time I think I shall not press this point now.

I just took this attitude on the majority report because I thought that this whole subject should be brought out into the light of day, so to speak. Please be assured that I do not wish to break down the clinics; I desire to put them on a sound basis of service to the indigent or near indigent. I have been with the state cancer program from the beginning — now seventeen years. I want to continue but I also want to do so in good conscience.

I want to say, in conclusion, that we cannot govern the State Department of Public Health, and it is to promote the discussion of this problem that I am asking your opinion today.

Dr. Bagnall spoke as follows:

As a matter of attitude as a member of the Council, my feeling is that we should go 51 per cent of the way in co-operation with the Department of Public Health. As a member of the Public Health Council I feel that I want to go at least 51 per cent of the way in co-operation with the Massachusetts Medical Society, and I know that that is the attitude of the Public Health Council, as well as of the Commissioner.

If you remember the phrasology of this law, it states that the Department of Public Health shall operate a clinic for cancer with or without the co-operation of organized medicine. So far as the legal angles are concerned, I think the suggestion of Dr. Truesdale is an excellent one. It is difficult for a body of this sort to get down to the important fundamental factors that would put us in position to decide what we ought to do. It must be apparent to all of you that that is necessary. That is why I should leave it to the members of the committee.

I have not heard Dr. Hunt say anything about a memorandum that the Commissioner published; but Dr. Lombard, at my request, produced it. It is to the effect that when patients are referred to the clinics by the attending physicians, the latter shall have a chance to follow the medically indigent. The clinics are instructed by the Commissioner and Dr. Lombard to inquire about the medical indigency of those patients who come in, who filter in through the family physician, and to direct that those people go to a private physician. That seems to be an answer to the statement that the state is practicing medicine on those who are not medically indigent.

In the matter of fee, Dr. Hunt, I think, contends only for two things. One is that we be not put in competition with ourselves so far as taking people who are not medically indigent is concerned. I think the Department of Public Health and the Committee on Cancer have definitely taken that stand and are in agreement. The only thing that remains then, is whether we have a \$2 fee, as Dr. Hunt asks, or a \$10 fee.

The \$10 fee does not cover the cost. The cost of any patient on the average is more than \$20, as all the facts show on the basis of medical indigency. I am very sure that, if \$10 is too high a fee, there can be an adjustment between the Department of Public Health and the Massachusetts Medical Society. Someone said that the intent of the law was that every patient should pay \$10. I think that is a mistake. The \$10 was stated as the fee, with gradations downward according to the degree of medical indigency.

There is another matter that perhaps you have not in mind but that I have in mind. I may be anticipating this. I have given it considerable thought and have not come to any fixed opinion. It has been stated that the Department of Public Health is presuming to direct the procedure that is offered in the State. The Department of Public Health would not have any right under those plans to reduce the fee of any patient by a dollar, even if he were not medically indigent.

With these general principles, we should be rather careful about taking any position hostile to the Department of Public Health. Perhaps I am not the man to say that but I do think that we can get along better with the department, and they with us, if we give and take and not throw brickbats.

Dr. Richard M. Smith assured the Council that the attitude of the Commissioner is not to attempt

any arbitrary procedure. He added that the plan proposed was the least objectionable of three possibilities. Finally, he expressed the hope that the Council would not take any decisive action.

Dr. William Dameshek, Norfolk, said that it seemed paradoxical to disapprove so overwhelmingly a medical program that had to do with socialized medicine and then to allow a plan of which the profession as a whole is ignorant. He mentioned that the Attorney General might allow the department, on the basis of this ruling, to put in clinics with reference to anemia or thyroid or renal conditions. He expressed as his final thought that this matter deserved further study on the part of the committee and Council.

Dr. Schadt said that, if this proposition was accepted, the Council might just as well accept the Wagner-Murray-Dingell Bill. He added, however, that he favored the majority report.

Dr. Hunt referred to the memorandum that Dr. Bagnall had previously mentioned. In reading it, he asked the councilors to listen carefully and see if they could make out what it meant:

Whereas, 85 per cent of the patients coming to the cancer clinics are referred by the family physician who knows whether these patients are able to afford full diagnostic service, the department recommends that of the 15 per cent of the patients applying directly to the clinic for diagnosis, those who upon investigation are found *not* to be in whole or in part unable to pay for their own diagnosis be referred to a private physician.

Dr. Hunt referred to Dr. Bagnall's statement that it costs \$20 per patient. He then read from the regulations as follows:

In this way the State pays for none of the services to individuals who can pay for themselves and only for a part of the services of "such persons as may be in whole or in part unable to support or care for themselves," as both physicians and hospitals contribute materially to all groups.

If it costs \$20 to see a patient, he continued, and the charge is only \$10, he did not see how the word "none" came in at all.

Finally, Dr. Hunt said that he had been in this work ever since it started and that he would be glad to continue but that he could not with a clear conscience continue to do so under these rules.

Dr. Leroy E. Parkins, Suffolk, moved as an amendment that the words "until the May meeting" be substituted for the words "for at least six months." This amendment was seconded by a councilor. It was adopted by vote of the Council.

The chair announced that the motion as amended read as follows:

It [the majority] recommends, however, that any action on these regulations by the Council of the Massachusetts Medical Society be postponed until the May meeting, so as to observe the manner in which the clinics function under these new regulations.

The motion as amended was put and was adopted by vote of the Council.

War Participation Committee—Dr. William B. Breed, Suffolk, chairman.

The report (Appendix No. 9) was offered by Dr. Breed. Dr. Breed moved that the report be accepted as a report of progress. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Committee on Rehabilitation—Dr. William E. Browne, Suffolk, chairman.
No report.

Postwar Loan-Fund Committee—Dr. George Leonard Schadt, Hampden, chairman.

The report (Appendix No. 10) was presented by Dr. Schadt, who moved its acceptance as one of progress. This motion was seconded by a councilor and it was so ordered by vote of the Council.

Military Postgraduate Committee—Dr. W. Richard Ohler, Norfolk, chairman.

The report (Appendix No. 11) was offered by Dr. Ohler, who moved its acceptance. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Committee to Aid the District Rationing Administrator—Dr. Joseph Garland, Suffolk, chairman.
Dr. Garland reported as follows:

Since its last report to the Council, this committee has met each month with the district rationing officer, aiding in various problems associated with the medical aspects of food rationing. In addition, the members of the committee have individually considered a number of doctors' certificates of patients' necessity. The excellent recommendations of the Subcommittee on Medical Food Requirements of the National Research Council, as published in the October 16 and 23, 1943, issue of the *Journal of the American Medical Association*, have been carefully studied, and have been adopted with liberal interpretations, so far as they have seemed to apply to local conditions.

A comprehensive report on the activities of the committee and the policies it has followed was published in the January 13, 1944, issue of the *New England Journal of Medicine*.

A problem was encountered in the request of the Moore Drop Forging Company, of Springfield, for extra meat allowances for several hundred of its employees who were working long hours at the open forge and in the heat treatment of metal. The request was made on the basis of undue fatigue and extreme loss of weight. It is interesting that no similar request, so far as can be ascertained, has been made by other plants of this type, here or elsewhere. As the decision in this case might be used widely as a precedent, however, advice was sought from the Harvard Fatigue Laboratory and the State Department of Public Health, and a hearing was held on January 5, 1944, at which your committee, officers of the regional and national OPA, and representatives of the Department of Public Health, the Massachusetts Department of Labor and Industry and the Harvard Fatigue Laboratory met with a medical representative of the Moore Drop Forging Company. No action favoring the request was taken, and the services of Dr. Robert S. Goodhart, chief of the Industrial Feeding Programs Division of the War Food Administration, have been enlisted to visit the plant and survey existing conditions.

FRANKLIN W. WHITE
F. GORIAN BRIGHAM
JOSEPH GARLAND, Chairman

Dr. Garland moved the acceptance of the report as one of progress. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Committee to Look into the Possibility of Better Publicity for the Massachusetts Medical Society — Dr. Albert A. Hornor, Suffolk, chairman.

No report.

Committee to Meet With the Trustees of Middlesex University — Dr. Reginald Fitz, Suffolk, chairman.

No report.

Committee on Postgraduate Instruction — Dr. Fitz, chairman.

No report.

Committee on Physical Therapy — Dr. Arthur L. Watkins, Middlesex South, chairman.

Dr. Watkins reported as follows:

In view of the value of physical therapy as an aid in the physical rehabilitation of industrial and war casualties, this committee has actively co-operated with the New England Committee for Wartime Graduate Medical Meetings in arranging monthly symposiums on physical therapy. Education of civilian and military physicians concerning the indications for physical therapy and the procedures to be prescribed appears especially important at this time. Future developments will be dependent on the role of civilian medicine in caring for the discharged service men. The Committee on Physical Therapy and the Rehabilitation Committee are working together and will be ready to provide advice and aid in whatever program is accepted by the Massachusetts Medical Society and the federal government.

Dr. Watkins moved the acceptance of this report as one of progress. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Committee to Consider Expert Testimony — Dr. Frank R. Ober, Suffolk, chairman.

No report.

Committee on Automobile Insurance Claims — Dr. Henry C. Marble, Suffolk, chairman.

No report.

Committee on Convalescent Care — Dr. T. Duckett Jones, Suffolk, chairman.

The Secretary announced that Dr. Jones had requested the discontinuance of this committee. The Secretary moved its discontinuance. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Committee to Study the Practice of Medicine by Unregistered Persons — Dr. Richard Dutton, Middlesex East, chairman.

No report.

Committee to Meet with the Massachusetts Hospital Association — Dr. Walter G. Phippen, Essex South, chairman.

No report.

Committee on Maternal Welfare — Dr. Judson A. Smith, Suffolk, chairman.

No response.

Committee on Ways and Means to Conserve Physicians' Energies — Dr. Elmer S. Bagnall, chairman.

No report.

APPOINTMENTS

President Lee made the following appointments of Delegates to the House of Delegates, American Medical Association, for two years beginning June 1, 1944:

<i>Delegates</i>	<i>Alternates</i>
David D. Scannell, Jamaica Plain	Elmer S. Bagnall, Groveland
Dwight O'Hara, Waltham	Ernest L. Hunt, Worcester
Charles E. Mongan, Somerville	Charles J. Kickham, Brookline
Walter G. Phippen, Salem	John I. B. Vail, Hyannis

Dr. William M. Collins, Middlesex North, moved that these appointments be confirmed. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Dr. Lee designated the following delegates to the annual meetings of the medical societies of the other New England states:

Maine: Warren H. Sherman, Lowell, and Frank W. Snow, Newburyport
New Hampshire: Peirce H. Leavitt, Brockton, and Daniel J. Ellison, Lowell
Vermont: George D. Henderson, Holyoke, and George L. Steele, Springfield
Rhode Island: George A. Buckley, Brockton, and Charles D. McCann, Brockton
Connecticut: Clarence E. Burt, New Bedford, and Edward P. Bagg, Holyoke

It was moved and seconded that these nominations be approved. It was so ordered by vote of the Council.

Dr. Lee appointed Dr. Reginald Fitz as delegate to the Annual Congress on Medical Education and Licensure, American Medical Association. It was moved and seconded that this appointment be confirmed. It was so ordered by vote of the Council.

Dr. Lee made the following *ad interim* appointments:

Committee to Look into the Possibility of Better Publicity for the Massachusetts Medical Society: Albert A. Hornor, chairman; Michael A. Tighe, Robert N. Nye, Norman A. Welch, Walter H. Pulsifer.
Committee to Meet with the Trustees of Middlesex University: Reginald Fitz, chairman; Robert T. Monroe, Daniel B. Reardon, Donald Munro, Harold L. Musgrave, Dr. William E. Browne, representing Suffolk, to the Committee on Legislation.

It was moved and seconded that these appointments be approved. It was so ordered by vote of the Council.

NEW BUSINESS

Dr. Jacob Fine, Suffolk, was recognized by the chair. Dr. Fine spoke as follows:

The Council may be interested in certain data regarding the foreign physicians licensed in Massachusetts. According to the *American Medical Directory* and the files of the

Boston Committee on Medical Emigres a total of 163 foreign physicians were licensed to practice in this state since 1934. The Committee on Medical Emigres has data in its files on all but 35 of the total number — that is it knows the type of activity and the location of settlement of 130 of them. They are distributed as follows: 40 hold institutional positions exclusively, 66 practice a specialty or are in general practice in large or medium sized cities, and 23 practice in small towns. They are settled in all parts of the State. Of the total number, 72 are members of the Society and 92 have not been admitted.

With these facts in mind the following questions present themselves:

(1) Have any of the 72 foreign physicians who are members of the Society and who became members before the amendment to the by-laws was adopted acted unethically? Have any of them acted so as to prejudice the interests of the Society, their fellow practitioners or the profession at large?

(2) Of the 92 foreign physicians who are not members of the Society, all but 5 have been licensed for two or more years. Twenty-four hold institutional positions, 68 are in various specialties and general practice. Of this group of 68, have any acted during these two or more years in such a way as to prejudice the interests of their fellow practitioners or the profession at large?

The Committee on Medical Emigres has received complaints in three instances, in one case it could not get sufficient information, in a second, in which the physician was undesirably publicized in a newspaper shortly after his settlement, there was evidence that the physician was taken in by an overzealous young lady reporter apparently anxious to get material, and in the third case now under investigation, the evidence is incomplete and conflicting, but the weight of evidence from the community itself is overwhelmingly in the physician's favor.

Rumors, vague accusations and generalizations regarding the demerits of these foreign physicians have been numerous, but specific demonstrable incidents of unacceptable practices have been exceedingly scarce and not out of proportion to what we experience among native born physicians.

At the annual meeting in May, 1942, 44 per cent of those voting on the amendment to the by-law disapproved it. The Committee on Medical Education unanimously disapproved it. The machinery for excluding undesirable physicians from the Society existed before the amendment was adopted.

What experience does the Society or the profession have before or since the adoption of the amendment that justifies its continuance in its present form? The threat of inundation of the State by foreign physicians was never real, and today there is only a rare individual who might settle here even if he were encouraged to do so.

It therefore seems appropriate for the Council to consider whether or not the amendment to the by-law is unnecessarily restrictive in its five year exclusion provision.

Dr Fine moved that the Committee on Membership be instructed to reinvestigate the merits of the five-year exclusion provision of the recent amendment with a view to reducing the time after a license is granted before membership in the Society is permissible. This motion was seconded by a counselor, and it was so ordered by vote of the Council.

Dr Phippen said that, when he was president of the Society, he had expressed the hope that when sufficient space was available an information bureau at the headquarters might be established. He added that there was now plenty of space. He moved that the President appoint a committee, which would include the Secretary, to study the question of establishing a bureau of information and its proper location in the Boston Medical Library. This motion was seconded by a counselor, and it was so ordered by vote of the Council.

There being no other business, the Council adjourned at 1:50 p.m.

MICHAEL A. TIGHE, Secretary

SCHEDULE A: Statement showing the balance sheet of The Massachusetts Medical Society, December 31, 1943.

SCHEDULE B: Statement showing the revenue and expenses of The Massachusetts Medical Society for the twelve months ended December 31, 1943.

The cash balance at December 31, 1943 was verified by direct correspondence and reconciliation. The cash receipts as recorded have been deposited in the bank, and disbursements are supported by vouchers or cancelled checks.

The securities and savings bank books were examined or accounted for.

The Building Fund and General Fund securities are listed in separate exhibits showing book and market values as of December 31, 1942 and December 31, 1943.

The market prices were furnished by Loomis-Sayles Inc. who also submit quarterly the average yield for both the Building and General Fund investments.

The profit or loss on securities sold, called or matured of the Building Fund and General Fund is shown under separate exhibits. The income from securities has been properly accounted for. During 1943, there has been no amortization of bond premiums.

The accompanying balance sheet and related statement of revenue and expenses fairly present the position of the Massachusetts Medical Society at December 31, 1943, and the results of operations for the year ended on that date.

Respectfully submitted,
HARTSHORN AND WALTER

50 Congress Street
Boston

APPENDIX NO. 2

REPORT OF THE AUDITING COMMITTEE

The Auditing Committee appointed the firm of Hartshorn and Walter, accountants and auditors, to audit the books and accounts of the Massachusetts Medical Society.

The accountants have submitted to us an analysis of the revenues and expenses of the Society and a balance sheet of the condition of the Massachusetts Medical Society as of December 31, 1943.

We have examined their report and the various schedules submitted.

perfections which did not permit military service were found in 17 per cent. Such a rejection rate among doctors who have applied for commissions is about standard.

As can be seen, on the whole, older men have been retained as essential physicians and younger ones have gone into military service. Persons inclined to disparagement have suggested that too many young men are being declared essential by special interests. This thought is not borne out by this analysis. The curve of essential men bears an almost direct ratio to length of time from graduation. Older men are not considered available, and only a few younger men are considered essential. This general trend is unmistakable. It is believed to reflect the experience of the entire state.

It is difficult to perceive how many more practicing physicians can be withdrawn from their homes without serious difficulty to the civilian population. In fact, the work of your

FIGURE 1. *The Classification of the Graduates of a Medical School Who Live and Practice in Massachusetts.*

committee is now becoming more and more concerned in attempts to place doctors in areas within the Commonwealth where the civilian population has come to consider itself medically shorthanded. The committee has been able to lend a helping hand in certain instances. In general, to keep accurate track of the medical migrations that are occurring is a difficult matter. Each local chairman is on the alert, however, keeping his eye on the situation within his district. At present, there is believed to be no serious medical shortage in any part of the Commonwealth.

The January 12 number of the *New England Journal of Medicine* gave an admirably succinct account written by the secretary of the Society of the recent change in policy regarding the awarding of commissions to graduates of substandard schools in Massachusetts who are licensed to practice here. A ruling from the Surgeon General's Office that prevents such men from receiving commissions in the future has caused a good deal of confusion. Many patriotic young men who hoped to obtain commissions on the completion of their internships were disappointed. In the main, such men have behaved extremely well. Many are continuing to serve as residents or interns in hospitals badly needing them, regarding such service as their contribution to the war effort. Others have opened offices in areas claiming to need physicians, and few, if any, have been drafted by Selective Service as privates.

The 9-9-9 plan for interns and residents has gone into effect commencing, as do so many new undertakings, with many

creakings. The establishment of a quota of interns in hospital approved for intern training appears to have enabled certain institutions to obtain a fairer share of this commodity than they did a year ago, although how satisfactorily is less certain. There seems to be developing a tendency for many hospitals to conserve a resident staff independent of the 9-9-9 plan by employing young physicians — women, foreign or physically rejected men — who are not of potential use for military service. Thus, the hospitals of Massachusetts have asked for the deferment of but relatively few commission officers. The majority of deferment requests that were submitted before the deadline of November 15 were accepted by the Surgeons General. The first activation of this plan has appeared to yield reasonably promising results.

Bearing in mind the influenza epidemic of twenty-five years ago, your committee is formulating plans with the War Participation Committee by which a type of emergency medical service can be established in this state that will be able to reach any region where it might be needed at any time. Your committee also is working with the Commissioner of Public Health to systematize the relocation of physicians for civilian practice under Public Law 216, signed by the President on December 23, 1943. As the details of these two undertakings are perfected they will be appropriately announced.

APPENDIX NO. 7

REPORT OF THE COMMITTEE APPOINTED TO CONSULT WITH REPRESENTATIVES OF THE OTHER NEW ENGLAND STATE MEDICAL SOCIETIES REGARDING THE WAGNER-MURRAY DINGELL BILLS

The initial conference with representatives of other New England state medical societies was held on September 2, 1943. At this conference, a great deal of wholesome discussion took place. Everybody had a chance to express his opinion and to express himself also as to the opinion of his respective colleagues in his own state. The consensus was that any criticism of proposed national legislation should be as constructive as we could make it and that flat-footed disapproval of the bill would be useless. Accordingly, the conference agreed to adjourn and to reconvene at a later date, and each member of the conference was asked to formulate some thoughts in the meantime.

In pursuance of this thought a second meeting was held on October 20 with the same group present except for the absence of Dr. Creighton Barker, of Connecticut. At this time, reports were made by all the members and, in particular, written reports were submitted from Rhode Island and Connecticut. At the close of the meeting the chairman was authorized to appoint a subcommittee to draw up a statement that could be submitted to the different medical societies for their approval. The chairman appointed Dr. James R. Miller, of Connecticut, and Mr. John F. Farrell, executive secretary of the Rhode Island Medical Society.

A third meeting was held on November 13. The prepared statement was read by Dr. Miller and Mr. Farrell and was gone over, sentence by sentence, in a long three-hour session. Not only was the subject matter very thoroughly discussed, but the exact wording of the sentences carefully scrutinized. Many changes and corrections were made in the original report. The statement was unanimously approved by all the members present and was agreed to also by the representative from Vermont, Dr. B. F. Cook, and by Dr. Barker, who were absent. It was agreed that this statement should be presented to the respective societies and if adopted by them, that it should be released to the press, to the *Journal of the American Medical Association* and the *New England Journal of Medicine*, and a copy sent to each senator and representative from New England. This statement was adopted by all the state medical societies of the New England states. Its language and structure has in no way been changed in its adoption. The statement is as follows:

MASSACHUSETTS MEDICAL SOCIETY
8 Fenway, Boston

December 2, 1943

Dear Sirs:

junction with the medical
Island and Connecticut
Bill 2861 now before the
submits its views on this
proposed legislation.

We approve of the broad medical objective of the act that we interpret
to be an attempt to improve the health of the people. As a basis of our
approval we cite the progressive leadership which the physicians of New
England have always shown in the development of public-health enter-
prise for

APPENDIX NO. 8

REPORT OF THE COMMITTEE ON CANCER

I transmit herewith majority and minority reports of the
Committee on Cancer together with enclosures—a copy
of the rules and regulations for state-aided cancer clinics as
of December 15, 1943, a specimen referral card to be issued
for the use of physicians sending cases to the clinics, and
an appendix embodying factual matter and opinions bear-
ing on that part of the regulations to which exception is
taken in the minority report.

I have felt it necessary to present a minority report because
of my conviction (1) that the propriety of final action upon
a question of public relations and economics by a committee
made up of technical experts in the field of cancer, most of
whom are affiliated with the cancer program of the Depart-
ment of Public Health, is questionable; (2) that a fee of two
dollars (\$10.00) is unnecessary and not in the public interest,
and (3) that so much feeling has been aroused that an ex-
pression of the collective wisdom of the Council is desirable
either to support the action of the Department of Public
Health and thus strengthen the position of those of us who
conduct the clinics against local criticism or, on the other
hand, to influence the department toward correction of the
point of contention, which, though small in fact, is large
in principle.

REPORT OF THE MAJORITY

On November 3, a letter from the Commissioner of Public
Health, Dr. Vlado A. Gettings, was received by the chairman
of the Committee on Cancer which read in part as follows:

As you no doubt know, the Department of Public Health
has, of necessity and in accordance with the laws of Massa-
chusetts, had to revise the regulations pertaining to the
cancer clinics. I should, therefore, appreciate an oppor-
tunity to appear before the Committee on Cancer at its
next meeting, in order to present these regulations to the
committee and to explain the reasons for their adoption
and the attitude of the department in this matter.

The request of the Commissioner was cordially received
by your committee and a meeting was held November 17,
1943, at the Harvard Club in Boston, all members of the
committee and the Commissioner being present.

At that time the Commissioner courteously explained the
circumstances making necessary the changes in methods
of administering the financial affairs of the state-aided clinics.

After the hearing the committee in executive session con-
sidered the regulations as amended. It was finally moved
by Dr. Simmons and voted:

The committee deplores the fact that changes have to
be made in the conduct of the state-aided cancer clinics
due to the interpretation of the Constitution of Massa-
chusetts by the Attorney General.

The majority of the committee believes that the regu-
lations presented are the best solution of the problem.

It recommends, however, that any action on these regu-
lations by the Council of the Massachusetts Medical Society
should be postponed for at least six months, so as to observe
the manner in which the clinics function under these new
regulations.

From this view, Dr. Ernest L. Hunt, chairman of the
committee, dissents.

FRANKLIN G. BALEH
CHANNING C. SIMMONS
PHILEMON E. TRUESDALE

REPORT OF THE MINORITY

The undersigned member of the committee, constituting
a minority, dissents from the opinion of the majority that
the rules and regulations as presented to the committee
"represent the best solution of the problem for the present."

The minority believes that the state-aided cancer clinics
should be operated within the obvious intent of the Con-
stitution (see "Appendix"), namely, that its services be lim-
ited to the indigent or near indigent, and if it is necessary to
exact fees from "such persons as may be in whole or in part
unable to support or care for themselves," such fees should
not be so large as to imply competition with private sources
of the same type of service, and patients, who pay ten dol-
lars or over should

The minority is in favor of sports be
accepted but that the recommendation of the minority be
adopted as expressing the opinion of the Council.

ERNEST L. HUNT, Chairman

NEW RULES AND REGULATIONS FOR CANCER CLINICS BY THE MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

The Cancer Clinic Regulations approved January 15, 1935, are hereby
rescinded and the following are substituted:

FOREWORD TO CANCER CLINIC REGULATIONS

Whenever possible, all patients shall be referred to the clinic by the
family physician, who may supply the clinic with the information re-
quested on the referral card, and who may furnish the clinic with in-
formation as to the patient's ability to pay in whole or in part the regular
clinic fee.

Referred patients will be returned for further diagnosis or treatment
to the family physician whenever the physician so requests.

CANCER CLINIC REGULATIONS

The Massachusetts cancer clinics are of two types: state cancer clinics
and state-aided cancer clinics.

A state cancer clinic is a medical unit furnishing consultation service,
diagnosis and treatment for persons suffering from precancerous con-
ditions, suspected cancer or cancer, under the exclusive control, order
and superintendence of the State Department of Public Health. This
type of clinic at present is held at Pondville and Westfield.

A state-aided cancer clinic may be defined as a medical unit furnishing
either consultation service alone, or consultation service, diagnosis
and treatment, for persons suffering from precancerous conditions, sus-
pected cancer or cancer, under the exclusive control, order and superin-
tendence of the State Department of Public Health. Such persons as may
be in whole or in part unable to support or care for themselves.

A committee composed of five or more physicians shall be appointed annually either by the local medical society or by the staff of a hospital. This committee shall be known as the cancer-clinic committee. The local organized medical group, through its cancer-clinic committee, may petition the State Department of Public Health to establish either a state cancer clinic or a state-aided cancer clinic. If a state cancer clinic is requested by the local group and approved by the department the cancer-clinic committee acts as an advisory body. If a state-aided cancer clinic is requested by the local group and approved by the department the cancer-clinic committee acts as an administrative body. The following rules and regulations apply to the state-aided cancer clinics:

The committee shall be responsible for all administrative matters pertaining to the clinic. These shall include the procurement of suitable quarters for the examination of the patients, preferably in a hospital, and the appointment and responsibility for the medical personnel, nurses, follow-up workers and clerical help of the clinic. Follow-up of cancer patients until death, and precancerous patients until the precancer is removed, and the maintenance of a uniform record system are required.

The committee shall make arrangements with the hospital in which the clinic meets to furnish examination rooms, instruments, diagnostic x-rays and other essential equipment and supplies.

At least three physicians should be present at each clinic session and shall preferably be a surgeon, a radiologist and a pathologist. If available, representatives of the various specialties shall be on call.

A nurse is to be in attendance at all clinics.

A clerical worker shall have charge of the clinic files and furnish such reports through the district health officer as may be requested. Uniform record forms will be supplied to the clinics.

Each clinic is to employ a "cancer clinic follow-up worker." This individual will attend to the follow-up and related duties of the clinic. In some of the smaller clinics it may be well, for purposes of economy, to combine the duties of the follow-up worker and the clerical worker. The minimum qualifications for the follow-up worker shall consist of some previous exposure to medical and social problems, as well as some knowledge of the medical and social resources available in the community.

When a problem arises which calls for advice from a medical social worker, unless the cancer-clinic follow-up worker is a trained medical social worker approved by the department, a request for aid should be sent to the local district health officer.

All new appointments of clinic personnel shall be subject to the approval of the department. The department reserves the right to approve on a temporary basis the appointment of personnel who do not meet the minimum qualifications, and to approve other changes in the clinic, during the war emergency.

Individuals able to pay will reimburse the clinic for services. The standard fee shall be \$10.00, which will include all routine and subsequent follow-up services, *except the services of the physicians of the clinic staff and certain other hospital services, which are gratuitous.* Individuals unable to pay \$10.00 but able to pay some fraction of that amount shall do so. The department will pay for services rendered by the clinics for "such persons as may be in whole or in part unable to support or care for themselves." Each clinic shall determine which individuals are "in whole or in part unable to support or care for themselves." Clinics in hospitals which do not have a prescribed form for determining medical indigency, and clinics in those hospitals whose method is not approved by the department shall adopt the department method. This consists of a personal interview with the individual by the admitting officer. Due care in selection of the admitting officer is of utmost importance.

In order to make the payments equitable for all clinics differing in size and services rendered the following procedure for payments has been adopted:

Each clinic shall submit monthly a list of services rendered the preceding month. Unit values have been determined for the ordinary services rendered by a cancer clinic. These are termed service units. The service units are totaled for each clinic and then converted into payment units. The payment units of all clinics, with the exception of those which, because of balances due to donations of clubs, individuals, community chest, legacies and other sources, do not need current payments, are totaled. The money available for the clinics for a given month is divided by this figure to determine the monetary value of a payment unit. This figure multiplied by the number of payment units for a given clinic minus the money received from patients who pay all or part of the \$10.00 fee furnishes the amount of clinic payment to be made by the State. In this way the State pays for none of the services to individuals who can pay for themselves and only for a part of the services of "such persons as may be in whole or in part unable to support or care for themselves," as both physicians and hospitals contribute materially to all groups.

The chief of each clinic shall furnish a monthly report, made under penalty of perjury, listing the units of work done by the clinic, the amounts received from patients who can pay all or a part of the \$10.00 fee, and the statement, "The clinic is billing the State only for the services rendered, to the best of our knowledge and belief, to such persons as may be in whole or in part unable to care for themselves." On the invoice submitted for payment the statement shall be appended, "This bill is submitted for payment of services only for 'such persons as may be in whole or in part unable to care for themselves.'"

If major changes in the management of a clinic are contemplated, the approval of the Department of Public Health should be obtained.

The Department of Public Health reserves the right to have its representative make regular inspections of the clinics and make suggestions for improved service. It may cease purchasing service from a clinic which fails in its obligations to the public.

When a clinic ceases to sell service to the State, either by a vote of the local group which originally sponsored it, or by a vote of the Department of Public Health, it is the responsibility of the department to follow the cancer patients previously seen at the clinic, until death. Arrangements must be made either with other clinics, district health units or voluntary agencies of the Advisory Cancer Clinic Committee, to see that this is done.

REVERSE OF CARD

THE BEARER IS NOT IN THE POSITION TO PAY FOR PRIVATE CONSULTATION

1. He is able to pay full clinic fees.

2. He is able to pay partial clinic fees.

3. He is unable to pay any clinic charge.

Fees collected from patients are to pay in part for the maintenance of the clinic. The services of the physicians and those controlled by the hospital are gratuitous.

APPENDIX

New rules and regulations for the government of the state-aided cancer clinics were issued early in October, which contained the following provision for collecting fees from patients applying for clinic service:

Individuals able to pay will reimburse the clinic for services. The standard fee shall be \$10.00, which will include all routine diagnostic services and all subsequent follow-up services. Individuals unable to pay \$10.00, but to pay some fraction of that amount, shall do so. The department will pay for services rendered by the clinic for such "persons as may be in whole or in part unable to support or care for themselves." Each clinic shall determine which individuals are "in whole or in part unable to support or care for themselves."

Another paragraph further provided that the funds so realized should be applied toward the expenses of the clinics while the services of the medical staffs continue voluntary and gratuitous, thus in effect extending medical charity beyond the patients to the treasury of the Commonwealth.

On November 4, the Worcester Clinic Committee convened for the purpose of considering the new regulations, voted its disapproval of that section on the ground that the State Department of Public Health would be "obviously selling the services of physicians who themselves are donating their services" and asked for its clarification.

At the hearing before the Committee on Cancer on November 17, the Commissioner very courteously explained the circumstances making necessary the changes in methods of administering the financial affairs of the state-aided clinics. In brief, it appears that prior to the present commissioner's appointment to office certain legal opinions had been rendered to the effect that the method of financing the clinics through subsidies, which had been in practice since their inception, was illegal. Consequently a special act (House 1387) was passed by the Legislature validating all expenditures that had been made by the department in support of the clinics. A new plan was then set up by the department to purchase the services of the clinics for the patients and an elaborate system of unit values was devised and put into operation. The new plan was reviewed by the Attorney General's office and also declared to be illegal because it was in violation of Article XLVI, Section 3, of the amendments to the Constitution of Massachusetts, which section reads:

Section 3. Nothing herein contained shall be construed to prevent the Commonwealth, or any political division thereof, from paying to privately controlled hospitals, infirmaries, or institutions for the deaf, dumb or blind not more than ordinary and reasonable compensation for care or support actually rendered or furnished by such hospitals, infirmaries or institutions to such persons as may be in whole or in part unable to support or care for themselves.

As a result of these legal opinions the department considered that it had three possible alternatives for administering the clinics: they could be restricted to the service of the medically indigent only; they could be put on a fee basis and the doctors paid; or the clinic could serve the medically indigent gratis and collect fees from those able to pay.

The objection to the first plan was that cancer is not limited to the indigent, and it is the job of the department to fight cancer. To the second was the objection that if all clinic doctors were paid the funds available would not be sufficient. The third plan, which seemed to the Public Health Council most feasible, was consequently adopted and the maximum fee of ten dollars decided on and approved by the Attorney General.

The Commissioner then presented to the committee a revision of the regulations in which the paragraph under question was changed to read:

Individuals able to pay will reimburse the clinic for services. The standard fee shall be \$10.00 which will include all routine and follow-up services, except the services of the clinic staff and certain other hospital services, which are gratuitous. Individuals unable to pay \$10.00 but able to pay some fraction of that amount shall do so. The Department will pay for services rendered by the clinics for "such persons as may be in whole or in part unable to support or care for themselves." Each clinic shall determine which individuals are "in whole or in part unable to support or care for themselves."

The revision by dropping the word "diagnostic" and adding "except the services of the clinic staff and certain hospital services, which are gratuitous" aims to make it clear to the patients that the charges are only for the clinic overhead and not for the services of the doctors and nurses.

To further emphasize the fact of the gratuitous service of the medical staff, the Commissioner presented a revision of the referral card which physicians use in sending patients to the clinic in which the doctor is asked to certify that the patient is not able to pay for private consultation and to express his opinion as to the patient's ability to pay clinic fees. To this the Commissioner agreed to add in bold type the words:

Fees collected from patients are to pay in part for the maintenance of the clinic. The services of the physicians and those contributed by the hospital are gratuitous.

This aims to impress on both the referring doctor and the patient who brings in the card the fact that he is receiving gratuitous services from the medical staff of the clinic.

The Commissioner expressed the opinion that the fee of \$10.00 would act as a deterrent to abuse of the clinic staff charity. He also felt that the certification asked of the referring doctor to the effect that the bearer is unable to pay for private consultation or able to pay the clinic fee or certain fractions thereof or unable to pay anything would automatically eliminate the person able to pay \$10.00, who would naturally prefer a private consultant.

The majority of the committee concurred with the views of the Commissioner.

The minority contends that the section of the constitution quoted above clearly defines the group which is now comprehended by the term "medically indigent" as those for whom the state may properly purchase medical services. A device for extending medical service beyond the clear intent of the constitution strikes at the foundation of orderly and controlled government.

The present is a moment fraught with grave threats to the economic freedom of the medical profession. Throughout the land feeling runs high against further state and institutional encroachments on major fields of private medical practice. Any unnecessary aggravation of this feeling now is both untimely and unwise.

In many sections of the state a fee of \$10.00 is equivalent to the usual private consultation fee. To establish such a fee standard for clinic services, however it serves expediency, is of itself a clear bid for patronage by persons above the economic level of those unable or nearly unable to support or care for themselves and will tend to alienate the support of the medical profession from the cancer program and to embarrass the professional relations of those members of the clinic staffs who from loyalty to the program elect to continue in the work.

ERNEST L. HUNT, Chairman

APPENDIX NO. 9

REPORT OF THE WAR PARTICIPATION COMMITTEE

Late in the fall of 1943 the committee instructed its chairman to undertake a survey of the distribution of active practicing physicians in Massachusetts with particular reference to the number per thousand of population in the various districts, as well as in the Commonwealth as a whole. Accordingly, the district chairmen of the committee were instructed to prepare such surveys with the assistance of the local Procurement and Assignment committees. To date complete reports have been received from only six districts, namely, Barnstable, Bristol North, Hampshire, Worcester North, Middlesex East and Norfolk South — a disappointing number. Few reports of civilian doctor shortage, however, have come to the attention of this committee, and we believe that at the present time no emergency exists. Some relocation of physicians has been executed by the State Procurement and Assignment Committee at the request both of local communities and of individual doctors seeking a settlement; as of this date all major community requests have been satisfied. There has existed from the beginning the closest co-operation between our War Participation committees and the Procurement and Assignment committees on the district as well as on the state level.

At a meeting of the War Participation Committee on January 30, 1944, it was the consensus that plans should be entertained to meet the possibility of an outbreak of a serious epidemic of disease. In spite of the fact that there is no large area within the Commonwealth that is at present medically short-handed, it was considered wise for the Society to be prepared for such an outbreak, when civilian needs for emergency medical care might become acute in several areas at the same time.

Various schemes were considered, prominence being given to the plan of the Worcester District Medical Society described by Dr. J. J. Dumphy in the *New England Journal of Medicine*, issue of January 7, 1943, and to the so-called "San Francisco Plan," both of which present certain features that

CASE 30131

PRESENTATION OF CASE

A twenty eight year-old housewife entered the hospital because of pain in the right hip

The patient was in apparent good health until about six years before admission, when, without antecedent trauma, she developed a dull ache in the right thigh and leg. The pain was not influenced by weather, but was aggravated by hard work and relieved by bed rest. It gradually increased in severity and the thigh became the area of maximal pain. About two years before entry, during the course of pregnancy, the pain became quite severe. Following successful delivery of a normal infant, the pain seemed to subside for a while. Gradually, however, it again increased in severity, although there were some symptom free days. She noted progressive limitation of activity so that by the time of admission she could not scrub the floor or climb more than one step at a time. She walked with a limp.

There was no history of tuberculous contact or of cough, sputum, hemoptysis, increased night sweats, chills, fever or urinary symptoms.

*On leave of absence

Physical examination showed a well developed, well-nourished woman in no distress. The heart, lungs and abdomen were normal. There was tenderness over the right ischial tuberosity and over the inferior iliac spine, and considerable spasm of the right hip muscles. Some atrophy of the right thigh muscles was present without any difference in the length of the two extremities. The right hip was painful on flexion past 95°. Flexion was limited to 100°. Because of pain, internal rotation was limited to 15°, and external rotation to 10°. Full extension was possible.

The blood pressure was 135 systolic, 85 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood showed a white cell count of 11,200 with 78 per cent neutrophils. The hemoglobin was 13.6 gm per 100 cc. A blood Hinton test was negative. The sedimentation rate was 4 mm in fifteen minutes, 6 mm in thirty minutes, 13 mm in forty-five minutes and 19 mm in sixty minutes. The blood uric acid was 4.0 gm per 100 cc.

An x ray film of the chest was negative. X-ray films of the pelvis showed a number of round cyst-like areas of diminished density lying in the wall of the right acetabulum (Fig 1). These measured from 0.2 to 1 cm in diameter and were surrounded by a zone of increased density. There was also generalized increase in the density of the bone throughout the region of the right acetabulum. In the lower margin of the head of the right femur, where it joined the neck, there was a similar area of diminished density with surrounding reaction. The joint space was markedly narrowed superiorly, and there appeared to be some destruction of the wall of the acetabulum medially. The right femur was held in slight adduction. The left femur and the remaining bones of the pelvis were normal.

On the fourth hospital day, an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. W. A. ROGERS: May we see the x-ray films?

DR. LAURENCE L. ROBBINS: This is the lesion as described, with areas of rarefaction scattered through the wall of the acetabulum and the head of the

FIGURE 1. Roentgenogram of Ilium.

femur, and apparently involving the upper portion of the neck of the femur. So far as I can see, the rest of the bones appear normal.

DR. ROGERS: In considering a joint condition, an orthopedist is by experience forced to consider all the possibilities because of the common lack of the typical for any given condition in the roentgenogram. One may say immediately from the history and the roentgenogram in this case that we are not dealing with a slipped upper femoral epiphysis. We are not dealing with Legg-Perthes's disease, nor are we dealing with congenital dysplasia of the hip. The radiographic appearances of each of these three diseases are sufficiently typical to justify their exclusion in this case.

I am impressed by the diffuseness of the sclerosis. In the iliac side of the joint the sclerosis extends

quite high and is not the typical subchondral type of sclerosis that we commonly associate with strain due to mechanical fault in the joint. I am also impressed by the cystlike areas of diminished density, and by the circumstance that these are of rather scattered distribution. This one is rather high which is not especially remarkable, but also along the upper portion of the neck of the femur there are cystlike areas of diminished density, which lie beneath the capsule of the joint, and one wonders what they are doing there. In cases of degenerative arthritis we see cystlike areas of diminished density in the roentgenogram, but they are usually limited to the head of the bone—not on the acetabulum side—and are closer to the joint. I am also impressed by the circumstance that there is evidence of destruction in the medial portion of the joint—that is, the vertical inner wall of the hip joint. The destruction is not confined to one side but is on both sides. In a degenerative arthritic process one would expect that the smooth line of the bone comprising the two sides of the joint would pass almost completely around the extent of the joint. In this case the line is sharply broken medially and is on both sides. The joint line is extremely thin. It is so narrow that it could be due to a traumatic arthritis with destruction of the articular cartilage from bad mechanics, or due to destruction of the cartilage, such as one might see in an infectious process, either acute or chronic.

In considering these punched-out areas, the narrowing of the joint line and sclerosis, one naturally wonders if the patient might not have had gout, but in gout there is usually no history of almost continuous pain, varying in degree, to be sure, but from day to day and in direct proportion to activity. In gout, as we all know, there is generally a story of attacks with remissions of relative comfort. Furthermore, the blood uric acid level was well within normal limits, and the patient was not febrile, nor was there a leukocytosis.

The question of rheumatoid arthritis must be faced, and one is immediately impressed on examining these films with the rather diffuse sclerosis rather than diffuse atrophy. The irregularity in the joint line in a rheumatoid condition can be localized to a limited portion, but it is usually less of an excavation, more fuzzy, and not so deeply penetrating. Furthermore, the sedimentation rate did not exceed normal. It was high normal to be sure, but not what one would expect with rheumatoid arthritis, and I gather from the history that this was a single-joint affair.

One must also consider, of course, the Neisseria joint, and not be deterred from that diagnosis by the sclerosis—at least this is true of the sacroiliac joint. The irregularity of the joint line, with destruction of the cartilage and even subchondral bone, and some irregularly punched-out areas in the joint are not inconsistent. The most conspicuous

feature of the Neisserian sacroiliac joint is diffuse sclerosis, which may extend back several centimeters on each side, and here we have, in a way, the picture of a Neisserian joint. She had had this, however, for six years, and she had a range of motion from normal extension to 100° of flexion. She had definite internal rotation of 15° , which is within normal limit, and 10° of external rotation. One would think that, in a Neisserian joint of six years' duration, the motion would be considerably less free than it was in this case. Pain was a conspicuous feature, and although an acute Neisserian joint is something to be reckoned with from the standpoint of pain, after six years one would expect a rather quiescent, relatively immobile, if not actually fused, joint.

The streptococcus and staphylococcus have to be considered, but by and large one is not inclined to follow up that line of thought because there is no dislocation, there is no extensive lesion of the head of the bone, and the joint line is smooth on top; these are strongly against such a lesion, although a low-grade infection by either might produce this picture. Furthermore, most streptococcal or staphylococcal hip joints are fulminating affairs.

We must always consider tuberculosis in a chronic joint, and there are many features in this case that suggest this diagnosis. If this were a shoulder joint, it would be extremely likely. The shoulder joint being a nonweight-bearing joint, is not subjected to as much strain as the hip is, especially in women, and one might conclude that this was a caries sicca in the humerus and scapula. There are various irregularities about the joint, with extensive sclerosis, the destruction of the joint line is likewise in accord with a chronic, destructive, infectious process, which could be tuberculosis. The old concept that tuberculosis is a purely destructive disease from the standpoint of bone changes is not tenable. Areas of diffuse sclerosis of bone are extremely frequent, especially in the vertebral bodies, where sclerosis has been demonstrated to be the result of local anemia of the bone, the anemia resulting from thrombi that form in the local arterioles. With lessened blood supply the usual bone response is sclerosis.

We then come to a consideration that must be taken seriously — traumatic arthritis of the hip joint. The history does not contain a record of antecedent trauma. That does not mean, of course, that such trauma had not occurred. In dealing with joints, it is not uncommon to get a history similar to this one with respect to trauma, only to discover that one is dealing with a traumatic arthritis. By putting it up a bit more forcibly to the patient, trauma that had slipped the memory is often recalled. The prompt recovery from such trauma in adolescence is to be expected, followed by a slowly progressing degeneration of both sides of the joint.

In summary, I have seriously considered a Neisserian joint, a tuberculous joint and a traumatic

arthritic joint, nonrheumatoid and nonconstitutional, of course. My first choice, based on the diffuse sclerosis, the joint destruction and the presence of cystlike areas over an extensive zone, is tuberculosis. My next choice is traumatic arthritis.

DR. BENJAMIN CASTLEMAN: Dr. Smith-Petersen, will you tell us what you thought before operation and what you found at operation?

DR. MARIUS N. SMITH-PETERSEN: Our pre-operative diagnosis was low-grade infection in the anterior third of the ilium, directly above the acetabulum and in the roof of the acetabulum, with secondary synovitis of the joint itself and possibly with strain, secondary to faulty position of the hip — in other words, traumatic arthritis. The cystic areas that appear to be in the head of the femur and that seem to be due to bone atrophy are misleading. We were able to demonstrate these cysts at the time of operation, and they were actually in the acetabulum.

At the time of operation the roof was excised and the lower cystic areas cut across, releasing cheesy, putty-like material. The outstanding features of the joint itself were the many villi, particularly in the anterior portion of the joint. These villi were firm and dark brown, and when cut across, were fibrous in character. They were firmer than the villi commonly seen in villus arthritis or traumatic arthritis, but since the duration of symptoms was six years, we came to the conclusion that this was an old synovitis with villus formation, the recurring synovitis having become increasingly fibrous in character. The postoperative diagnosis was simply a villus condition of the synovia, with cysts of unknown origin in the anterior third of the ilium.

CLINICAL DIAGNOSIS

Multiple cysts of ilium, due to low-grade infection, with secondary synovitis.

DR. ROGERS'S DIAGNOSIS

Tuberculosis of hip?
Traumatic arthritis?

ANATOMICAL DIAGNOSES

Pigmented villonodular synovitis of right hip.
Osteoarthritis of right hip.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: As Dr. Smith-Petersen has said, all these villi were reddish brown and firm. On microscopic examination they showed a marked increase in the stromal cells, numerous giant cells of the foreign-body type and large deposits of hemosiderin within the phagocytes and within the stromal cells (Fig. 2). In some areas the tissue was made up of so-called "foam" or xanthoma-like cells — that is, phagocytic cells filled with fat. Nowhere was there evidence of tuberculosis.

On the fourth hospital day, an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. W. A. ROGERS: May we see the x-ray films?

DR. LAURENCE L. ROBBINS: This is the lesion as described, with areas of rarefaction scattered through the wall of the acetabulum and the head of the

FIGURE 1. Roentgenogram of Ilium.

femur, and apparently involving the upper portion of the neck of the femur. So far as I can see, the rest of the bones appear normal.

DR. ROGERS: In considering a joint condition, an orthopedist is by experience forced to consider all the possibilities because of the common lack of the typical for any given condition in the roentgenogram. One may say immediately from the history and the roentgenogram in this case that we are not dealing with a slipped upper femoral epiphysis. We are not dealing with Legg-Perthes's disease, nor are we dealing with congenital dysplasia of the hip. The radiographic appearances of each of these three diseases are sufficiently typical to justify their exclusion in this case.

I am impressed by the diffuseness of the sclerosis. In the iliac side of the joint the sclerosis extends

quite high and is not the typical subchondral type of sclerosis that we commonly associate with strain due to mechanical fault in the joint. I am also impressed by the cystlike areas of diminished density and by the circumstance that these are of rather scattered distribution. This one is rather high which is not especially remarkable, but also along the upper portion of the neck of the femur there are cystlike areas of diminished density, which lie beneath the capsule of the joint, and one wonders what they are doing there. In cases of degenerative arthritis we see cystlike areas of diminished density in the roentgenogram, but they are usually limited to the head of the bone—not on the acetabulum side—and are closer to the joint. I am also impressed by the circumstance that there is evidence of destruction in the medial portion of the joint—that is, the vertical inner wall of the hip joint. The destruction is not confined to one side but is on both sides. In a degenerative arthritic process one would expect that the smooth line of the bone comprising the two sides of the joint would pass almost completely around the extent of the joint. In this case the line is sharply broken medially and is on both sides. The joint line is extremely thin. It is so narrow that it could be due to a traumatic arthritis with destruction of the articular cartilage from bad mechanics, or due to destruction of the cartilage, such as one might see in an infectious process, either acute or chronic.

In considering these punched-out areas, the narrowing of the joint line and sclerosis, one naturally wonders if the patient might not have had gout, but in gout there is usually no history of almost continuous pain, varying in degree, to be sure, but from day to day and in direct proportion to activity. In gout, as we all know, there is generally a story of attacks with remissions of relative comfort. Furthermore, the blood uric acid level was well within normal limits, and the patient was not febrile, nor was there a leukocytosis.

The question of rheumatoid arthritis must be faced, and one is immediately impressed on examining these films with the rather diffuse sclerosis rather than diffuse atrophy. The irregularity in the joint line in a rheumatoid condition can be localized to a limited portion, but it is usually less of an excavation, more fuzzy, and not so deeply penetrating. Furthermore, the sedimentation rate did not exceed normal. It was high normal to be sure, but not what one would expect with rheumatoid arthritis, and I gather from the history that this was a single-joint affair.

One must also consider, of course, the Neisserian joint, and not be deterred from that diagnosis by the sclerosis—at least this is true of the sacroiliac joint. The irregularity of the joint line, with destruction of the cartilage and even subchondral bone and some irregularly punched-out areas in the joint are not inconsistent. The most conspicuous

lost about 25 pounds over a period of three years. Her appetite had been good. The past history was otherwise negative.

Physical examination showed a well-developed, well-nourished woman without any evidence of recent weight loss. She spoke in a whisper and was in no distress. The neck veins were distended, particularly on the left. The left supraclavicular fossa appeared fuller than the right, but no masses were palpable. The lungs were clear and resonant

FIGURE 1.

throughout. The heart was enlarged to 2 cm. to the left of the midclavicular line in the fifth interspace. The sounds were of good quality and regular. A blowing systolic murmur was heard all over the precordium. The liver was palpable two finger-breadths below the right costal margin and was slightly tender. Superficial varicosities were seen over the abdomen and the lower extremities. There was no edema. Neurologic examination was negative except for a slightly diminished pharyngeal reflex and deviation of the tongue to the left. Repeated laryngeal examinations revealed the left vocal cord to be immobile and in the cadaveric position. No masses, ulceration or tubercles were seen on the cords or the subglottis. The arytenoids appeared normal and fairly movable.

The blood pressure was 130 systolic, 70 diastolic. The temperature was 100°F., the pulse 80, and the respirations 20.

Examination of the blood showed a red-cell count of 3,500,000, with 10.5 gm. of hemoglobin. The white-cell count was 6450. The urine was normal. A blood Hinton test was negative. The stools were negative.

An x-ray film of the chest (Fig. 1) showed a rounded area of increased density in the anterior portion of the left upper lobe at the level of the second rib. The heart was not enlarged. There was no definite widening of the aorta or evidence of aneurysm or a mediastinal tumor. A swallow of barium passed through the esophagus without hesitation at any point. An x-ray film taken two weeks later revealed a slight decrease in the size of the area of increased density. The left half of the diaphragm was somewhat elevated, but both leaves moved fairly well on respiration and there was no paradoxical motion.

A tuberculin test in dilution of 1:100,000 was positive. The venous blood pressure in the antecubital veins at the level of the sternomanubrial junction was equivalent to 7.2 cm. of water on each side. Repeated sputum examinations for tubercle bacilli were negative. An electrocardiogram showed normal tracings. The temperature remained about 100°F.

The patient did not seem to have much pain. Her voice improved transiently following laryngoscopic examination. She was discharged and told to return in four weeks for re-evaluation of her symptoms.

Second admission (two and a half months later). Following discharge the patient continued to have pain in the anterior chest and between the shoulder blades. She presented herself in the Out Patient Department about four weeks following discharge and was found to be fibrillating. An x-ray film of the chest showed no change from the previous examinations. During the next four or five weeks her condition gradually became worse, the pain increasing in severity. She had considerable cough, with dyspnea and occasional palpitation. The sputum was blood tinged. She had been given 1 gr. of digitalis every four hours for some weeks without apparent change. About one week before re-admission a scheduled bronchoscopy was postponed because she was fibrillating at a rate of 140, without noticeable dropped beats. She was given three doses of 2 cc. of Cedilanid within twenty-four hours and 1½ gr. of digitalis daily. Thereafter she continued to fibrillate, but at a rate of 100. Her condition otherwise remained essentially the same.

Physical examination on admission showed the diaphragm to be high on the left. Resonance was diminished over the left upper lobe posteriorly. Coarse rhonchi were heard throughout the chest, with stridor. The heart was slightly enlarged. The apical first sound was rough. The heart was fibrillating at a rate of 88, without a deficit. There was slight ankle edema.

The temperature was 100°F., the pulse 88, and the respirations 25. An x-ray film of the chest (Fig. 2) showed considerable fluid in the left pleural cavity. There was also density extending upward and outward from the hilus into the left upper lung field. The heart and mediastinum were displaced to the right.

The day after admission she was bronchoscoped. The left main bronchus was almost completely occluded by a mass arising in the lateral and anterior walls, leaving a 1-mm. opening. The mass was slightly irregular and reddish. A biopsy from the lateral wall was followed by an immediate massive hemorrhage, and 1500 cc. of blood was lost before

FIGURE 2.

it could be stopped. The pulse and blood pressure became imperceptible, but returned with the cessation of bleeding. She was given several transfusions and intravenous fluids. Examination following this episode showed dullness and flatness below the level of the sixth dorsal vertebra on the left posteriorly, with diminished breath sounds and many coarse tracheal bubbles throughout. The heart was fibrillating at a rate of 140, with a pulse deficit of 20. Pathological examination of the specimen revealed no diagnostic abnormality. Three chest taps in the course of the next eighteen days yielded about 700 cc. of bloody fluid. No micro-organisms, including acid-fast bacilli, or tumor cells could be found in the sediment. The fibrillation continued, the temperature ranged about 100°F., and she had considerable cough productive of a large amount of blood-streaked sputum. She went progressively down hill and on the twenty-first hospital day had sudden respiratory difficulty, accompanied by profuse sweating. She died a few minutes later.

DIFFERENTIAL DIAGNOSIS

DR. PAUL ZAMECNIK: If we summarize all the apparently pertinent findings at the time of the first admission, we find that they point to the region of

the arch of the aorta or to the left main-stem bronchus. In the first place the patient complained of difficulty in speaking, and we note that she had paralysis of the left vocal cord, which is consistent with paralysis of the left recurrent laryngeal nerve. Then she had cough, and fullness in the right supraclavicular region, and the neck veins were more distended on the left than on the right. She had pain in the sternum and between the shoulder blades. Finally, an x-ray film of the chest showed a rounded area of increased density in the anterior portion of the left upper lobe at the level of the second rib.

I wonder if we may see the x-ray films.

DR. MILFORD SCHULZ: These are the films made at the time of the first admission. You can see the indefinite area of increased density in the left upper chest. Whether that is infiltration or atelectasis, I do not know. The left leaf of the diaphragm appears to be elevated. Incidentally, the protocol did not mention it, but on fluoroscopy there was paradoxical motion.

DR. ZAMECNIK: But the diaphragm did move?

DR. SCHULZ: Yes. You can see a fair left main-stem bronchus on the oblique film. The impression was that the lesion had regressed, which I believe is partially due to technical difference in the films.

These films made at the time of the last admission show a marked change; the area of density has greatly increased.

DR. ZAMECNIK: How about this area?

DR. SCHULZ: It looks like a mass in the left mediastinum. In this film of the chest there is a large amount of fluid on the left side and a curious nodulation throughout the entire right lung field, not present previously.

DR. ZAMECNIK: Would you like to say anything more about these abnormalities? Do they look like metastatic disease?

DR. SCHULZ: They could be due to metastatic disease, but there are several other possibilities.

DR. ZAMECNIK: In attempting to explain the patient's downhill course and the cause of her death, let us focus our attention first on the most important single piece of information available — the findings of the bronchoscopic examination. "The left main bronchus was almost completely occluded by a mass arising in the lateral and anterior walls, leaving a 1-mm. opening. The mass was slightly irregular and reddish."

If we eliminate aneurysm as a cause of this woman's difficulties, we can confine our attention to tuberculosis and neoplastic diseases. The negative Hinton reaction, the lack of hypertension, the absence of an aortic diastolic murmur, the lack of pulsation in the sternal notch, the inability of the X-ray Department to find widening of the aorta and the unlikelihood that an aneurysm would produce such a localized invasion of the anterior and lateral bronchial walls make aneurysm a remote possibility.

The tuberculin test was found positive in 1:100,000 dilution. This reaction is interpreted as evidence that a person harbors a tuberculous lesion somewhere in the body, but it does not determine whether the lesion is active or healed. Certainly the x-ray picture of the chest is not suggestive of tuberculosis, unless it is a tuberculoma, which seems to be too rare a bird on which to pin a diagnosis in the face of data suggesting neoplastic disease.

One may divide neoplastic diseases into two groups, benign and malignant. Among the benign tumors of the lung and mediastinum are: dermoid cyst, neurofibroma, lipoma, adenoma and chondroma. The first three arise in the mediastinum and it is unlikely that they would invade a bronchus; the last two might arise in a bronchus. All these are relatively slowly growing tumors, which ordinarily produce pressure symptoms for months or years before becoming serious problems. The disease under discussion, on the other hand, was a rapidly progressive one. The fever, anemia and pleural effusion fit a little better with a malignant neoplasm of the chest than they do with a benign lesion.

The malignant diseases of the chest include lymphoma, carcinoma, sarcoma, teratoma and metastatic carcinoma or sarcoma. The mass seen by bronchoscopy appeared to arise near the left main-stem bronchus. Primary carcinoma of the lung is a frequent disease, accounting for 5 to 10 per cent of all deaths from cancer. In about 75 per cent of the cases, the original site is one of the main-stem bronchi. Except for the negative biopsy, therefore, the picture is a classic one for bronchiogenic carcinoma.

Metastatic carcinoma is, to be sure, an even commoner disease, but the metastases are usually, although not always, found in the periphery of the lung, and are often multiple. Furthermore the site of origin is usually the source of other signs and symptoms of the disease, which are absent in this case. There is therefore no advantage in choosing metastatic carcinoma over primary carcinoma, and there are definite disadvantages in such a selection.

Lymphoma is a great imitator, but the absence of splenomegaly (the spleen is not mentioned in the history), of peripheral adenopathy and of a symmetrical mediastinal enlargement deprives it of any positive support. Teratoma is a rare disease that is statistically unsound to diagnose, unless there is x-ray evidence of bone or tooth formation within the tumor mass. Primary sarcoma of the lung is likewise rare.

In summary, then, the evidence is consistent with the diagnosis of bronchiogenic carcinoma of the left main-stem bronchus, with mediastinal invasion causing paralysis of the left recurrent laryngeal nerve, and with pleural invasion. The cause of the fibrillation can be explained in one of two ways. First, it may have been due to the strain imposed on an aging heart by a severe anemia, or second, it

may have been due to infiltration of the pericardium and cardiac musculature by neoplastic disease.

DR. AUSTIN BRUES: I saw this patient for the first time when she was in shock following the bronchoscopy. For obvious reasons, most of which Dr. Zamecnik has given, it seemed that the lesion was probably a neoplasm and most likely carcinoma.

She was referred to the X-ray Department for an opinion whether, when she was in better condition, she might not get some x-ray therapy on the chance that this was a radiosensitive lesion. As I remember it, the radiologist who was consulted made the sensible observation that if this were tuberculosis it would probably be the wrong thing to do. We therefore made an effort to rule out tuberculosis and succeeded in doing so only by getting a considerable number of negative examinations for tubercle bacilli.

DR. HELEN PITTMAN: I saw the patient in the Out Patient Department when she came in complaining of shortness of breath and with a story of continued blood-spitting. I decided that all the signs added up to a bronchial neoplasm and referred her for the bronchoscopy that nearly exsanguinated her.

CLINICAL DIAGNOSIS

Carcinoma of lung.

DR. ZAMECNİK'S DIAGNOSES

Carcinoma of lung, left main-stem bronchus, with extension to mediastinum and pleura.

Auricular fibrillation due to anemia or metastatic carcinoma of pericardium or myocardium.

ANATOMICAL DIAGNOSIS

Epidermoid carcinoma of lung, left main bronchus, with metastases to mediastinal lymph nodes, pleura, pericardium, right lung and liver.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASRLEMAN: The autopsy on this woman showed that the lesion seen through the bronchoscope was a carcinoma that had extended into the lung for quite a distance and had infiltrated the left side of the mediastinum, completely surrounding but not invading the ascending aorta, part of the arch, with its branches, and the superior vena cava. The left recurrent laryngeal nerve was deeply imbedded in the tumor. The tumor had also extended along the lymphatics of the pericardium. Many small neoplastic nodules were present on the visceral pericardium, and a few were found on the parietal layer. The pericardial cavity contained 500 cc. of bloody fluid, as Dr. Zamecnik suggested. The arrhythmia may have been due to the pericardial involvement; the myocardium was normal. There were metastases to the liver and to the right lung. The recent lesions on the right side observed in the last roentgenograms were lymphatic metastases. The tumor was epidermoid carcinoma.

One interesting point in the history was the hoarseness. If one can rule out aneurysm, as Dr. Zamecnik did, the most frequent cause of hoarseness associated with a mediastinal lesion is carcinoma, rather than the other types of malignant disease. Lymphoma, for instance, frequently surrounds the recurrent laryngeal nerve but rarely infiltrates sufficiently to produce hoarseness. Would you agree to that, Dr. Aub?

DR. AUB: I have never observed hoarseness in a case of lymphoma.

DR. EDWARD B. BENEDICT: I have seen it once with tuberculosis.

DR. WILLIAM BECKMAN: How do you account for the fact that the patient's voice improved temporarily?

DR. BRUES: I do not know that she ever fully recovered her voice.

Was this a radiosensitive tumor?

DR. CASTLEMAN: The epidermoid carcinomas respond moderately well — not so well as the oat-cell carcinomas, but much better than the adenocarcinomas.

DR. ZAMECNIK: Was the phrenic nerve involved?

DR. CASTLEMAN: No.

CARTHAGO DELEND EST

WHEN Joshua blew his trumpets before Jericho, according to a source of information usually considered reliable, the walls came tumbling down. Troy went up in flames after the fifth column of the Greeks had penetrated its inner defenses. Nineveh and Tyre became one with the pomp of yesterday, and the merciful jungle has crept in to cover the bones of many an ancient city. After the second Punic War, when Hannibal had finally been driven from Italy, the elder Cato had only one ending for his speeches: *Carthago delenda est* — Carthage must be destroyed; and eventually that city, which had threatened the security of Rome, was erased from the map so thoroughly that corn could be planted over its ruins.

History repeats itself. Germany, for a century the scourge of Middle Europe, had prepared herself and had every intention of waging a destructive warfare on her European neighbors, if not on all the world that resisted her. Warsaw was destroyed. Rotterdam was laid waste in cold cruelty, after its surrender; the same would have happened to the cities of England if Goering had not overestimated the power of the *Luftwaffe*.

After years of desperate heroism the tide has turned, and it is the nations allied against Germany that have the mounting air power to destroy the cities of that rebellious nation. Berlin is being laid waste, and the job will be carried through to the finish. A moral question is now being raised, and many shocked persons, here and in England, are crying out against the violence and the mercilessness of this growing counterattack. We must not put ourselves in the category of those who make war on civilian populations, they say, and vengeance belongs to the Lord. (There is an equally applicable aphorism that those who live by the sword must perish by the sword.) That able commentator, Raymond Gram Swing, has taken occasion to answer these horror-stricken protestants: in the destruction of Berlin we are not primarily making war on her civilian population, on her women and children, but we are seeking to destroy Germany's power to make war against the world.

These pacifistic peacemakers are not the only ones who have feelings of guilt over the course the war has taken; millions of us have feelings of remorse. But they are not concerned with the destruction of Berlin; they are over our failure in the past to have taken the obvious steps necessary to prevent this war from breaking out at all. They are because we failed to prevent Japan from taking Manchukuo; because we failed to protect Ethiopia from Mussolini; because we failed to save Czechoslovakia from Hitler in 1938. These are the misdeeds that we should repent — to have failed then to use force in order to prevent this violence now.

CONTROL OF CANCER

MASSACHUSETTS has always been a pioneer in public-health matters, and through the efforts of

seventeen years, ably assisted by the medical profession of the Commonwealth, as well as by the Committee on Cancer of the Massachusetts Medical Society, which was appointed in 1917, the adjusted mortality rate for women from this disease in Massachusetts has shown a distinct drop, which is not the case throughout the country.

The program of the Department of Public Health consists of educational campaigns, a pathological diagnostic service, research work, cancer clinics and the maintenance of two hospitals adequately staffed and prepared to treat the disease by all known modern methods.

The federal government is also interested in the control of the disease. The United States Public Health Service is co-ordinating the activities of the various cancer programs in the country and, in addition, supplies radium to certain hospitals and conducts extensive research work in the National Cancer Institute at Bethesda, Maryland.

The American College of Surgeons has devoted much effort in stimulating the establishment of cancer clinics, in surveying and improving existing cancer clinics and in preparing uniform records. It has established a minimum standard for the conduct of these clinics, which are modeled after those inaugurated in Massachusetts.

The American Society for the Control of Cancer, established thirty years ago, has been a leader in the campaign against this disease. It is active in states not having an adequate cancer program, and in certain other states it supplements the work of public-health or other organizations carrying on a campaign for the control of the disease.

The sinister nature of cancer in its late stages is everywhere recognized, but much still remains to be done to convince the general public that periodic examinations by a physician comprise one of the most useful methods for the control of cancer. The present war provides no excuse for lessening the anti-cancer fight, and it is to be hoped that members of the medical profession will continue to educate their patients and the public at large concerning the value of the early recognition of suspicious symptoms by means of regular physical examinations. Furthermore, this effort should be redoubled during April, which has been designated "Cancer-Control Month" by a proclamation of the President.

MEDICAL EPONYM

GRAWITZ TUMOR

"Die Entstehung von Nierentumoren aus Nebennierengewebe [The Origin of Renal Tumors from Adrenal Tissue]" is the title of a paper read by Paul Grawitz (1850-1921), then assistant in the Pathological Institute in Berlin, on April 17, 1884, at the Thirteenth Congress of the Deutsche Gesellschaft für Chirurgie. This paper was published in the *Archiv für klinische Chirurgie* (30:824-834, 1884). A portion of the translation follows:

I shall try to show that such fetal anomalies not only occur, but do so with a frequency that exactly corresponds with the frequency of accessory strumas; then I shall explain the location of the strumas from the location of this sort of supernumerary bits of adrenal tissue; then, from the microscopic appearance controvert the assumption that the urinary tubules can be the matrix of the tumors; and finally, demonstrate the correspondence of these strumas with such growths, which quite evidently have originated from the adrenal glands.

DEATH

STONE — Ralph E. Stone, M.D., of Beverly, died March 22. He was in his sixty-seventh year.

Dr. Stone received his degree from Harvard Medical School in 1905. He was a member of the staffs of the Beverly Hospital, the Cable Memorial Hospital, Ipswich, and the North Shore Babics Hospital, Salem, and was consultant physician for the New England Industrial School for the Deaf. He was a member of the Massachusetts Medical Society, the American Medical Association, the National Tuberculosis Association, the Beverly Chamber of Commerce and the Harvard Club of the North Shore.

His widow survives.

PERFORATION OF THE ILEUM FOLLOWING LATE ILEOSTOMY FOR ULCERATIVE COLITIS*

JOHN H. CRANDON, M.D.,† THOMAS D. KINNEY, M.D.,‡ AND IRVING J. WALKER, M.D.§

BOSTON

THE treatment of intractable, chronic, non-specific ulcerative colitis by surgery in the form of ileostomy has been advocated in recent years by many surgeons as a means of arresting the disease. McKittrick and Miller,¹ Lahey,² Cave,³ Jones⁴ and others have reported marked success with this operation, but each has been careful to point out that when employed in the terminal stages, ileostomy is accompanied by an extremely high mortality rate. The present paper is a report of 2 cases illustrating a hitherto undescribed complication of late ileostomy for ulcerative colitis.

Both cases presented are similar in that death was due to generalized peritonitis following perforation of an ulcerative lesion of the ileum. In each case the perforation occurred above the site of ileostomy, the points of perforation being 15 and 6 cm., respectively, above the ileostomy openings. Grossly, the terminal ileum in each case showed a diffuse ulcerative process similar to that seen in the colon. The ulcers in the ileum were sharply demarcated and varied in size and shape, and the intervening mucosa was swollen. Microscopically, the mucosa was absent or necrotic, and there was edema and thickening of the submucosa, together with marked polymorphonuclear leukocytic and lymphocytic infiltration of the submucosa and of the mucosa at the ulcer edge. In the deep ulcers there was similar leukocytic infiltration of the muscularis. The pathologic findings, in other words, were identical with those found in the colon in chronic ulcerative colitis.

Because of the frequency with which the disease process extends into the terminal ileum in the later stages of the disease, the question arises whether in the present cases the disease process did not exist in the ileum above the site elected for enterostomy

at the time of operation. This question is reasonable because in each case ileostomy was performed close to the ileocecal valve. Certainly the perforations were not related directly to the ileostomies, since these patients lived seven weeks and eight and a half weeks, respectively, after operation.

Supportive evidence that disease existed proximal to the site of ileostomy before operation in each of these patients was the early postoperative course, for the ileostomy drainage never became solid but remained liquid and profuse. This was in marked contrast to the early postoperative course of other treated patients who survived, for in these cases the drainage began to solidify by the end of the second postoperative week. In addition, in Case 2, old healed ulcers were found in the terminal ileum above the ileostomy at autopsy.

Extension of nonspecific ulceration of the terminal ileum in patients suffering from chronic ulcerative colitis is fairly well known but has not received sufficient emphasis. In order to determine the frequency of this lesion in the ileum, 16,500 consecutive autopsies from the files of the Mallory Institute of Pathology, Boston City Hospital, were reviewed. Including the present cases, there were 44 cases in which chronic ulcerative colitis was considered to be the primary cause of death. In 17 of these, or 39 per cent, there was involvement of the small intestine. In the majority of cases the ulcerative process was confined to the terminal ileum—that is, to the lower 30 cm. of the ileum. In 3 cases, however, the ulcers extended throughout the lower third of the ileum. The incidence of perforation was striking. There was perforation of the colon in 7 cases (16 per cent), whereas perforation occurred in lesions of the small intestine in the 2 operative cases described and in 2 other cases in which fistulas developed from ulcers in the terminal ileum and jejunum. In other words, the incidence of perforative lesions of the small bowel in cases in which there was ulcerative colitis was 24 per cent, or one and a half times greater than the incidence of perforative lesions of the large bowel.

*From the Fifth Surgical Service (Harvard) and the Mallory Institute of Pathology, Boston City Hospital, and the Department of Surgery, Harvard Medical School.

†Formerly, assistant in surgery, Harvard Medical School; and resident, Fifth (Harvard) Surgical Service, Boston City Hospital.

‡Assistant professor of pathology, Tufts College Medical School, instructor in pathology, Harvard Medical School, assistant pathologist, Mallory Institute of Pathology, Boston City Hospital.

§Clinical professor of surgery, emeritus, Harvard Medical School, consulting surgeon, Boston City Hospital.

It is evident from a study of this material that the danger of perforation in the terminal ileum is always present in cases of severe ulcerative colitis in which surgery is delayed. To reduce the danger of this complication it seems wise always to do an ileostomy at least 90 cm. above the ileocecal valve and to avoid operative procedures on the terminal ileum. If a low ileostomy has been carried out and the fecal discharge remains loose and profuse, the possibility of ulceration of the terminal ileum above the ileostomy should always be kept in mind so that if acute abdominal symptoms develop, operative intervention can be immediately instituted. It should be possible in selected cases to visualize the terminal ileum before operation by barium and so to anticipate this complication.

CASE REPORTS

CASE 1. F. W. (B.C.H. 772,645), a 50-year-old, married man, was admitted to the medical service on January 8, 1935, complaining of rectal bleeding and frequent bowel movements. Three weeks before entry he began to have two to six bowel movements each day. The stools were loose and contained moderate amounts of bright-red blood. He was treated by his family physician with relief of symptoms, for 10 days. Three days before coming to the hospital, however, the symptoms returned in their original intensity and, in addition, there occurred gripping pains in the lower abdomen. On the day of entry, the patient felt weak and fainted twice. He had lost approximately 20 pounds during the previous 2 months. He gave a history of rheumatic fever associated with ulcers of the rectum and frequent loose, bloody stools 6 years prior to entry.

On admission the temperature was 100.2°F., the pulse 94, the respirations 22, and the blood pressure 120/80. The patient appeared to be fairly well nourished and of normal development. There was slight generalized abdominal spasm. On rectal examination there was marked spasm of the sphincter and there was blood on the examining glove, but no masses or ulcers were palpated. The remainder of the physical examination was negative.

The patient was treated on the medical service for 23 days without success. During that time the temperature fluctuated between 99 and 103°F. and the diarrhea became severer. While the patient was on this service, large punched-out ulcers on the rectal wall were demonstrated by sigmoidoscopy on two occasions. Two barium enemas were interpreted as showing marked spasm of the sigmoid, with diminished haustral markings and multiple irregularities of the transverse and sigmoid colon. In addition, there was a constant filling defect of the cecum.

On the 23rd hospital day, the patient was transferred to the Fifth Surgical Service for ileostomy. This was performed under spinal anesthesia on the day of transfer. At operation, the cecum and colon were found to be thickened and hyperemic. The external appearance of the terminal ileum was not noteworthy. A loop ileostomy was performed approximately 7 cm. proximal to the ileocecal valve. The patient withstood the operation well. During the next 5 days he continued to have diarrhea and began to suffer from crampy abdominal pains and vomiting. On the 5th postoperative day, the loop of the ileum was opened. Vomiting continued and the blood chlorides became depleted. This was corrected by administering intravenously large amounts of normal saline solution. The vomiting gradually decreased and the temperature gradually returned to normal, so that by the 34th postoperative day it was believed that the patient was definitely improved; however, the ileostomy discharge continued to be loose and the patient had occasional bloody movements by rectum.

On the 56th postoperative day, the patient again began to suffer from severe abdominal cramps and vomiting. His condition became progressively worse, and he died on the 60th postoperative day.

Laboratory studies during the hospital stay showed the red-cell count to be 3,000,000 and the hemoglobin 60 per

cent. The white-cell count varied between 10,106,700, with 70 per cent neutrophils, 17 per cent lymphocytes, 2 per cent monocytes and 1 per cent basophils. The cell morphology was not remarkable. Repeated urinations showed traces of albumin and many white and two specimens contained red cells. A blood Kal was negative. The skin reactions to 1:10,000, 1:100, 1:100 dilutions of tuberculin were negative. Agglutination tests against typhoid, paratyphoid and *Brucella* organisms were negative. Two blood cultures showed no growth. Stools were always guaiac positive, and microscopic examination revealed no ova or parasites. Repeated cultures of stools were negative for pathogenic organisms. A specimen of a rectal ulcer showed chronic inflammation.

Autopsy (35-202). At autopsy the body was that of a poorly nourished man. In the right lower quadrant, level of the anterosuperior spine of the ileum, were openings in the anterior abdominal wall, each 3 cm. in diameter and each containing an open end of ileum. Thru the peritoneal cavity 800 cc. of thick, bright, foul-smelling, purulent matter was found. Many loops of small intestine were matted together by fibrin, and in addition, other loops of small bowel were adherent to the ascending and descending colon and to the bladder and rectum. The small intestine was moderately distended. Ten to fifteen centimeters above the ileocecal valve and 15 cm. from the ileostomy wounds were two round perforations in the wall of the ileum, each approximately 1 cm. in diameter. Beginning at a point 60 cm. above the ileocecal valve and extending throughout the entire colon and rectum, there was a marked ulceration of the mucosa of the bowel. The ulcers varied in size, were clearly defined and irregular in outline, and had ragged, gray-black bases. In many areas the ulcers had been undermined, leaving bands of mucosa with attachment to underlying tissue. In some areas the ulcers were confluent so that the bowel wall was denuded of mucosa for a distance of 7 to 10 cm. The ulceration appeared of equal severity throughout the colon, but at the site of perforation in the ileum it was especially severe.

Sections of the ileum showed the mucosa to be covered by an exudate consisting chiefly of fibrin and polymorphonuclear leukocytes. The mucosa was ulcerated and this process extended into the muscularis. The muscularis and the muscularis were diffusely infiltrated by plasma cells and lymphocytes. Sections of the colon showed extensive ulceration of the mucosa and muscularis, with infiltration by plasma cells and lymphocytic infiltration.

Cultures of ulcers in the ileum and from the peritoneal cavity showed *Escherichia coli*, alpha-hemolytic and non-hemolytic streptococci and *Proteus vulgaris*. Type 8 *Staphylococcus aureus* was cultured from the heart's blood.

In addition to the lesions described, the patient was found to have bronchopneumonia of both lower lobes and pulmonary congestion and edema.

The anatomic diagnoses were ulcerative colitis, ulcerative ileitis with perforation, generalized peritonitis, bacterial pneumonia, and pulmonary congestion and edema.

CASE 2. H. S. (B.C.H. 987,922), a 44-year-old, white woman, was admitted to the medical service on June 1940, complaining of bloody diarrhea of 10 months' duration. She stated that she had had from fifteen to twenty bloody stools every twenty-four hours, and that the stools had contained bright red blood and occasionally mucus. In addition, she suffered from crampy pains in the umbilical region. She estimated that she had lost 20 pounds in weight during the course of her illness.

Physical examination on admission revealed a malnourished, poorly nourished, excitable woman who gave the appearance of being chronically ill. The temperature 100°F., the pulse 100, the respirations 16, and the blood pressure 125/85. The left ear drum was perforated. There was a short systolic precordial murmur. There was no ulceration of the cervix.

The patient was placed on a high-vitamin, low-calorie diet, supplemented by various vitamin preparations. She received bismuth subcarbonate and belladonna and there was a moderate decrease in the diarrhea. Proctoscopy showed multiple undermined ulcer craters with dirty-gray bases which bled easily. Scrapings from the craters were negative for amebae. The patient was given sulfathiazole, with some improvement, and because she developed toxic symptoms this drug was discontinued. Since all efforts to control

diarrhea were unsuccessful and the patient was obviously failing, she was transferred to the Fifth Surgical Service on the 59th day for ileostomy. At the time of transfer there was a foul, purulent vaginal discharge from a rectovaginal fistula.

Ileostomy was performed on the day of transfer under intravenous Pentothal Sodium anesthesia. The terminal ileum was divided 15 cm. from the ileocecal valve, and the distal end was brought through a separate stab wound in the McBurney area. At that time the serosal surface of the terminal ileum appeared normal.

The patient's postoperative condition was poor. The temperature was 102.4°F., the pulse 120, and the respirations 22. There was a persistent, profuse discharge from the ileostomy wound. Large quantities of normal saline solution were administered intravenously, and fourteen blood transfusions were given in an effort to maintain the total serum protein and hemoglobin, which averaged 4.5 gm. and 65 per cent, respectively.

Two weeks postoperatively, the patient developed severe, cramplike abdominal pains and began to vomit. The ileostomy drainage temporarily ceased. She was placed on Wangersten drainage and responded well, so that in 2 days all signs of obstruction had disappeared. Starting with the 4th postoperative week, her appetite became progressively poorer and it was necessary at times to resort to forcible feeding through an infusing Levine tube. Large doses of thiamine chloride and ascorbic acid were given daily.

During the 6th postoperative week, the patient developed signs of acute pericarditis, and this diagnosis was confirmed by x-ray. Purulent material was obtained on aspiration of the pericardium, and on culture *aureus*, fusiform bacilli and *taeni*. Pericardiostomy was performed and the patient remained in shock for five treatment, which included blood. At that time she also developed a panophthalmitis of the right eye. During the following 6 days the patient recovered from shock. The pericardial cavity was irrigated regularly. On the afternoon of the 6th day following pericardiostomy, the 49th day following ileostomy, she suddenly complained of pain in the right lower quadrant of the abdomen. Examination of this area showed tenderness and spasm. The pulse and respirations rose rapidly, the patient's condition generally deteriorated, and she died 12 hours later.

Autopsy (40-828). At autopsy the body was that of an emaciated woman. There was a recent open operative wound over the heart measuring 11 by 4 cm. Portions of the 5th and 6th ribs had been removed, leaving a window 4 by 4 cm., opening directly into the pericardial cavity. There was a well-healed scar of the right rectus muscle, as well as a healed ileostomy scar on the right. There was a patent ileostomy in the midline. When the peritoneal cavity was examined, the omentum was adherent to the ileum at a point 6 cm. above the ileostomy wound. A small perforation was found in the wall of the ileum at that point, and the serosal surfaces were covered with thick, fibropurulent exudate. There was 300 cc. of cloudy fluid flecked with fibrin in the lower abdomen and pelvis. *Staph. aureus* and alpha-hemolytic streptococci were cultured from this fluid. There were no further ad-

hesions, either old or recent, in the peritoneal cavity. The distal stomp of the ileostomy was well healed and was 8 cm. above the ileocecal valve.

The esophagus, stomach, duodenum, jejunum and proximal portion of the ileum were normal. Beginning at a point 15 cm. above the ileostomy were a series of approximately fifteen small ulcerated areas in the mucosa. These mucosal lesions had an irregular, punched-out appearance, and each measured approximately 4 mm. in circumference. There were a few dense white scars that apparently represented healed ulcers. One of the active ulcers had perforated as described above. The ileum distal to the ileostomy contained

areas from which mucosa at the edge of the ulcers and the muscularis underlying the base of the ulcer were infiltrated by lymphocytes and plasma cells.

Ulcerations were found in the ascending colon and rectum. The ulcers in the rectum were large and tended to coalesce so that large areas were denuded of mucosa, leaving the muscularis bare. Sections showed necrosis and sloughing of the mucosa. There was marked infiltration of the remaining mucosa by lymphocytes and plasma cells. These lesions were much severer than those seen in the ileum. *E. coli* and *Pseudomonas aeruginosa* were cultured from these ulcers. The rectum and vagina were adherent in places, and there were two small fistulas between these organs.

The epicardial and parietal pericardial surfaces were smooth or grossly thickened together, and a few bacteria.

In addition to the above lesions there was moderate atelectasis and a slight amount of bronchopneumonia in the right lower lobe.

The anatomical diagnoses were ulcerative colitis, ulcerative ileitis with perforation, peritonitis, purulent pericarditis (healing), pyohemothorax (left), atelectasis (left lower lobe), bronchopneumonia (left lower lobe) and rectovaginal fistulas.

SUMMARY

Two cases are described in which perforation of the ileum above the site of ileostomy with resulting peritonitis occurred following operation.

It is suggested that, in cases of prolonged severe ulcerative colitis, ileostomy, if indicated, be performed at least 90 cm. above the ileocecal valve.

heart, arrhythmias and electrocardiographic abnormalities, constitute a clinical picture that may appear indistinguishable from that of acute myocardial infarction. In order to make the correct diagnosis it is necessary to realize that the two conditions may resemble each other closely and then to consider certain of the features in detail. The differential diagnosis may be difficult. In 4 of the 5 cases described above a diagnosis of cardiac infarction was at first actually made or seriously considered, and in 3 of these 4 cases it was possible to discard the diagnosis of infarction only after careful observation. The following points have been found useful in differentiating acute pericarditis from acute myocardial infarction.

Pain. The distinguishing feature is accentuation of the pain by bodily movements, cough and inspiration. It is important to elicit the fact that characteristically the aggravation of the pain on exertion is not due to effort but to certain movements, such as turning over in bed. The aggravation of the pain by motion, cough and inspiration is present from the very outset in pericarditis, whereas when it occurs in myocardial infarction it is usually first noted twenty-four or forty-eight hours or more after the onset of the pain, and probably indicates that the infarct has extended to the pericardium or that some complication has arisen.

Dyspnea. Although dyspnea may be associated with pulmonary congestion, in most cases it can be ascertained that it is consequent to rapid, shallow breathing due to pain that interferes with the respiratory movements.

Pericardial friction rub. In most cases of myocardial infarction a friction rub is never heard; when present, it is rarely heard in the first twenty-four hours, is usually localized, and lasts only a short time. In acute pericarditis, on the other hand, the rub is heard within one to a few hours after the onset of pain, tends to be very loud, is audible over the entire precordial area, and is constantly present for days or for even one or two weeks.

Pleural involvement. Pleural involvement was demonstrated in 4 of the 5 cases of pericarditis by the presence of a pleural friction rub or by thickening of the pleura and a small collection of pleural fluid on x-ray examination. The fifth patient was not studied by x-ray.

Cardiac dilatation. The heart dilates in some cases of acute pericarditis² to a degree that exceeds that seen in myocardial infarction; nevertheless, myocardial failure does not occur in acute pericarditis. The only reliable method of detecting acute dilatation in these cases is teleroentgenography.

Abnormal ventricular pulsations. In 75 per cent of the cases of myocardial infarction a localized area of diminished, absent or reversed ventricular pulsations is found on careful fluoroscopic observation.³⁻⁷ No such abnormalities of ventricular pulsation were demonstrable in these cases of pericarditis.

Electrocardiograms. Characteristic electrocardiographic patterns occur in acute pericarditis and acute myocardial infarction; they are readily differentiated in spite of certain similarities. The pattern in acute pericarditis is sufficiently distinctive to permit the diagnosis to be made even in the absence of a pericardial friction rub. Elevation of the RS-T segment is not accompanied by reciprocal depressions, the ascending limb of the T wave is straight or concave upward or the T wave is dome-shaped, significant QRS patterns do not occur, and the evolution of the entire pattern with reversion to normal takes place in a matter of weeks.¹ To avoid overlooking the pattern of infarction, however, an electrocardiogram should be obtained as early as possible, and be frequently repeated until the diagnosis is established beyond any doubt. Multiple chest leads should be used.

Fever. When temperature elevation occurs in pericarditis, it may be noted at the very onset of the attack. It may reach a higher level and last much longer than is usual in cases of acute myocardial infarction.

Pulse rate. The slowness of the heart rate may be striking in pericarditis; the average heart rate is slower than it is in cases of myocardial infarction.

White-cell count. Leukocytosis may be much greater and may last much longer in pericarditis than in infarction.

Age incidence. The ages of the above patients with pericarditis were thirty, twenty-nine, thirty-two, forty-one and sixty-eight years, respectively, a lower average than one would expect in myocardial infarction.

Manifestations of infection. Chilliness, chills, a "grippy" feeling and actual respiratory infection were more numerous in this series than they are in cases of infarction.

DISCUSSION

The importance of not mistaking acute pericarditis for acute myocardial infarction needs little comment. The serious prognosis in the latter disease, the long period of incapacity and the frequent necessity of radically altering the patient's life contrast strikingly with the excellent prognosis and the expectancy of unrestricted activity in the former. In the one disorder there is always present the anxiety of some untoward event; in the other one can look into the future with confidence, even though recurrences of pericarditis occur in some cases.²

This problem in differential diagnosis has not been generally appreciated because of the belief that pericarditis usually or always occurs in association with rheumatic fever, tuberculosis, pneumonia, septic infections and cardiac infarction. The evidence warrants the assertion that in the cases here reported rheumatic fever, tuberculosis, septic infection and myocardial infarction can be excluded as etiologic factors. In Case 1 pericarditis complicated recovery

from primary atypical pneumonia; in Cases 2 and 3 it appeared without any previous illness or symptoms of infection, although pharyngeal injection was found in Case 2, and in Case 5 it occurred in an elderly man with chronic bronchial asthma. An unusual aspect in Case 4 was the coincidental presence of angina pectoris.

It is probable that the pericarditis in the cases here described was infectious in origin, although not of uniform etiology. With the onset of pericarditis in Case 4, manifestations of infection — that is, a "grippy" feeling, chill, a high white-cell count and marked febrile reaction — were prominent. Four or five attacks of pericarditis occurred during a seven-month period, illustrating, as did Case 2, the predisposition to recurrences. A benign, nonsuppurative, inflammatory pericarditis may apparently occur under various circumstances, unassociated with the commonly recognized causative factors. It may follow tonsillectomy. It has been reported following operative procedures^{8,9} and has been observed in epidemic form.¹⁰ Occurring as a postoperative complication and associated with a grayish pallor, a rapid, weak pulse and a drop in blood pressure, it may be erroneously diagnosed as pulmonary embolism or myocardial infarction.⁹

Barnes and Burchell¹ express the opinion that the correct diagnosis depends chiefly on the correct interpretation of the electrocardiographic changes, which they describe in detail. They do, however, consider the age incidence, the relation of the pain to inspiration and the marked cardiac dilatation as helpful in making the correct diagnosis. These, as

well as the other manifestations discussed above, should establish the diagnosis on a firm basis.

SUMMARY

Five cases of acute nonsuppurative pericarditis are reported in which the clinical picture strikingly simulated that of acute myocardial infarction. The latter diagnosis was at first erroneously made in 4 of them.

It is important to make the correct diagnosis, since in pericarditis prolonged and careful treatment is not necessary and the prognosis is excellent, in contrast with the seriousness of myocardial infarction.

The differential diagnosis is discussed and shown to be based on meticulous consideration of clinical, laboratory, electrocardiographic, teleroentgenographic and fluoroscopic data.

MEDICAL PROGRESS

DIABETES MELLITUS

ELLIOTT P. JOSLIN, M.D.*

BOSTON

ALLOXAN DIABETES

THERE are now three methods by which diabetes can be caused experimentally: the removal of the pancreas, discovered by von Mering and Minckowski; repeated injections of anterior pituitary extract, finally accomplished by Young but based on the work of Houssay, Evans and others; and the injection of a chemical — namely, alloxan. In the April 17, 1943, issue of the *Lancet*, Dunn, Sheehan and McLetchie¹ in Glasgow described how they had produced a selective necrosis of the islets of Langerhans of the pancreas in rabbits by injection with alloxan. Within a few weeks this paper was followed by others from groups from Chicago, Boston and

Glasgow, in which it was shown, as might be expected, that if the animals were kept alive, diabetes developed as a result of the necrosis of the islet tissue.

Chemically alloxan is the uride of mesoxalic acid, and as a result of its four carbonyl groups it is chemically a very active substance. Structurally it is closely related to the purines, particularly to uric acid. It may act either as a strong reducing agent or as an oxidizing agent. Its activity as an oxidizing agent is probably directly related to its ability to act as a hydrogen acceptor. As a hydrogen acceptor its affinity for the sulphydryl groups may be of particular biologic significance. Lehmann² found that alloxan inhibits the conversion of the Cori ester to the Robison ester and in higher concentrations the formation of the Cori ester itself.

Alloxan is readily soluble in water, forming a slightly acid solution. It is relatively stable only in acid solution. Labes and Freisburger³ suggest that the mild alkalinity of the blood and tissues is probably sufficient to cause decomposition of any free alloxan almost immediately unless it enters into some other reaction. Through reduction it becomes alloxantin, whereas through oxidation it changes to parabanic acid.

*Clinical professor of medicine, emeritus; Harvard Medical School; medical director, George F. Baker Clinic, New England Deaconess Hospital.

Alloxan is easily obtained from the oxidation of uric acid with nitric acid. Its relation to the role of uric acid in the body is, therefore, of possible significance. Uric acid in the human body originates exogenously in nucleoprotein in the food and therefore varies in amount according to the diet, but also originates endogenously. Uric acid eliminated in human urine amounts to 0.4 to 1.0 gm. daily, as compared with 20 to 35 gm. of the more highly oxidized urea. The excretion of uric acid is known to increase with muscle exercise. Muscle is not only the greatest consumer of sugar but is also the chief source of endogenous uric acid.

The deep significance of the production of diabetes by a chemical lies first in the simplicity and sureness of the method. Previous methods required technical skill or considerable time and labor. Furthermore, by pancreatectomy or by injections of mixed anterior pituitary extracts, other tissues than the insulin-producing islands were involved. Moreover, the use of the rabbit and rat affords animals easily available and suitable for research, thus opening up avenues for investigation of diabetes that were previously unavailable. The importance of the discovery merits a more detailed summary of these studies.*

In 1937, Jacobs⁴ found that alloxan produced fatal hypoglycemia when injected intravenously into rabbits. Microscopic studies of the pancreas were not made. Recently in studies on the crush syndrome and mismatched blood transfusions Dunn experimented with injections of uric acid, which he had previously observed caused a selective lesion in the distal convoluted tubules and collecting tubules and other allied substances. He noted that alloxan gave promising results but that the animals died within the first day or so with symptoms not referable to renal disease, and it was in the course of these investigations that a lesion was found in the islands of Langerhans.

In a protocol of one of the rabbits three doses of alloxan were given intravenously in half an hour, each dose amounting to 100 mg. per kilogram of body weight in a 2 per cent solution of distilled water. The next morning the rabbit was in a feeble state, and later it was comatose, with slow, feeble breathing. The rectal temperature, normally 102 to 103°F., was below 93°F. The animal was chloroformed and an autopsy performed twenty-eight hours after the beginning of the experiment; the blood urea was 101 mg. per 100 cc., but the blood sugar was only 59 mg. compared with a normal of 100 to 140 mg. The kidneys showed an early tubular nephritis. No changes in other organs were noted save in the pancreas. Dunn, Sheehan and McLetchie describe these as follows:

The acinar tissue appeared normal; some eosinophil casts were present in ducts. The islets of Langerhans were all

abnormal; in most of them there was complete necrosis of the central cells, leaving only a ring or a crescent of live cells at the periphery; rarely, all the endocrine cells were necrotic. The protoplasm of the dead cells had the characteristic appearance of coagulative necrosis and often their bodies had fused into a mass. The nuclei had lost all the normal basophil staining of chromatin and took on eosin more intensely than did the protoplasm; their edges were ill defined as if they were undergoing lysis. The surviving peripheral cells generally had nuclei of normal appearance, as had sometimes their protoplasm, but very often the cell bodies were somewhat swollen and definitely eosinophilic though evidently not necrosed; in some of these the nuclei were small and hyperchromatic.

In subsequent experiments death occurred in twelve to twenty-eight hours following the injection, save in one rabbit that was killed in forty-eight hours and another that was killed on the fifth day. All the rabbits injected with alloxan showed some degree of islet necrosis. The authors concluded that a single intravenous dose of 300 mg. per kilogram of body weight given to an adult rabbit of average nutrition could be depended on to produce an extensive lesion of the islands, with characteristic symptoms. The blood sugar, initially 100 to 140 mg. per 100 cc., rose considerably for the first one or two hours, reaching 380 mg. in one case, and then fell in three to five hours to 100, 50 or even 30 mg. The terminal phase may not always have been seen, the animal having been killed to ascertain the state of the pancreas. No glycosuria was detected in any of these animals.

These authors summarize their work in part as follows:

Acute necrosis of almost all the islet tissue of the pancreas has been observed in rabbits after intraperitoneal inoculation of a synthetic styryl-quinoline, and also after intravenous inoculation of alloxan. The development of this lesion is accompanied by an initial rise of blood sugar, followed by an intense hypoglycemia which ends fatally with subnormal temperature in twelve to eighteen hours. It is suggested that the lesion may be caused by overstimulation of the islets with overproduction of insulin, and later death of the cells from overstrain. The mechanism of production of the lesion is discussed and reference is made to the possible role of alloxan as a hormone of muscle.

* * *

In a letter to the editor of the *Journal of the American Medical Association*, Brunswick, Allen, Goldner and Gomori⁵ confirmed the work of the Glasgow observers and also stated that they had observed animals that survived injections of alloxan and exhibited only transitory hyperglycemia. They found that alloxan in doses of 200 to 500 mg. per kilogram of body weight was fatal to dogs in one hour to five days. They also noted that the transitory hyperglycemia was followed by hypoglycemia and by the end of forty-eight hours a pronounced hyperglycemia again occurred, which persisted in five dogs for two or three weeks. They also injected alloxan into 3 patients with carcinomatosis, apparently without much effect. In a subsequent communication, however, these cases and 2 others, in one of which the patient had an insulin-producing pancreatic carcinoma, were studied in detail by Brunswick, Allen, Owens and Thornton,⁶ who confirmed the earlier work in showing little influence of alloxan on the first 3 cases of noninsulin-producing cancer.

*Brief mention should be made of another chemical, styryl-quinoline No. 90, of which the full name is 2 (p-acetyl-amino-styryl) 6-dimethyl-amino-quinoline methochloride. According to Dunn, Sheehan and McLetchie, this substance, prepared by Cohen and Ellingworth, when tested by Brown and Gulbransen was found to have curative properties for infections with *Trypanosoma brucei*, but was inapplicable because it sometimes caused acute nephritis. In a subsequent study of this nephritis in rabbits, Sheehan observed that the animals lay prone with the hind legs stretched and the head tilted up ward, with rapid respirations. The blood examination revealed a rise of blood sugar as high as 500 mg. per 100 cc. and the animals died in twelve to eighteen hours. Histologic examination showed a necrosis of the islands of Langerhans. No distinctive lesions were found in any other organs save the kidneys.

The alloxan did show a distinct reduction in the hypoglycemic attacks of the patient with the malignant tumor of the islet cells. The patient had had marked attacks, dating as far back as 1937, and had undergone operations for these by removal of islet-cell nodules from the pancreas or liver in September, 1939, in January, 1940, in August, 1942, and finally in December, 1943. Temporary symptomatic relief of these attacks was obtained, since the attacks were obliterated for a brief period following each series of injections. Shortly after the last laparotomy, the patient succumbed to an accidental complication. Autopsy revealed multiple metastatic nodules within the liver. Sections of the surgically removed pancreas showed normal acinar tissue and no evidence of necrotic islet cells. Sections of the tumor nodules showed viable tumor cells and no evidence of necrosis comparable with that seen in the islet cells in the pancreases of dogs and rabbits receiving alloxan. There was no evidence of acute damage to the liver cells, and no necrosis of the epithelium of the convoluted tubules.

Two other features of this case deserve mention. First, as a result of repeated attacks of hyperinsulinism, a tolerance for low blood-sugar levels had developed and the patient was able to conduct himself normally with a level as low as 20 mg. per 100 cc., the attack level being 14 mg. or less. Second, forced ingestion of food in an attempt to ward off hypoglycemic attacks resulted in a 35-pound gain in weight over a period of seven months after the carcinomatosis of the liver was proved by laparotomy, thus suggesting, as the authors state, that the cachexia of carcinoma is merely the result of a gradual reduction of the caloric intake and not of a toxemia originating from tumor cells.

The fifth patient was given the largest single injection of alloxan of the entire group, and died six hours after termination of the injection. This patient had a large carcinoma of the lower rectum, which had been previously excised. The patient returned with various complications, and reacted with few symptoms on August 27, 1943, when he was given 200 mg. of alloxan per kilogram of body weight, dissolved in 1000 cc. of an isotonic solution of sodium chloride. On September 1, however, when he received 600 mg. per kilogram of body weight, dissolved in 1200 cc. of saline solution, he developed a moderately severe chill and cyanosis and some six hours later, having apparently recovered from the symptoms following the injection of alloxan, suddenly died.

* * *

If alloxan produces extensive necrosis of the islands of Langerhans without damage to its acinar tissue and relatively minor changes in other organs, so argued Bailey and Bailey,⁷ it would be reasonable to suspect that the hypoglycemic phase following the injection of the drug is transitory. Should this

prove to be true, animals kept alive by repeated injections of dextrose might survive this hypoglycemic phase and finally develop diabetes mellitus. A series of experiments designed to test this hypothesis showed that such is the case.

Three-month-old male Dutch rabbits were employed. Each received intravenously 200 mg. of alloxan per kilogram of body weight, the injection being given in three parts over a period of forty-five minutes. The rabbits were observed continuously for sixteen to twenty-four hours, and 50 per cent glucose was given intravenously whenever hypoglycemic convulsions occurred. These authors also found an initial transitory hyperglycemia lasting approximately one hour after the injection of alloxan, followed by severe hypoglycemia with convulsions, but in less than twenty-four hours the hypoglycemic stage ended, leaving the animals with severe diabetes. Blood-sugar levels during the diabetic state ranged from 360 to 700 mg. per 100 cc. and glycosuria up to 10 per cent. One rabbit not given insulin developed acetonuria, total acetone bodies of 144 mg. per 100 cc. and pronounced lipemia, with total blood lipids of 8412 mg. per 100 cc. Insulin, $1\frac{1}{2}$ to 8 units daily, was given to control the diabetes.

Two rabbits were killed, and it was found that the cells, both alpha and beta, of all the islands of Langerhans had completely disappeared. No polymorphonuclear infiltration was seen. The blood vessels of the islands were preserved and appeared entirely normal. Some of the pancreatic ducts were moderately distended and contained eosinophilic material. Their epithelium, as well as that of all the acini, showed no changes detectable on microscopic examination.

The following is a representative experiment in the series:

Rabbit 1, weighing 1520 gm., was entirely normal during a 7-day period of observation. Food was withheld for 18 hours, at the end of which time blood-sugar determinations were 105 and 100 mg. per 100 cc. (one hundred and four milligrams of glucose per 100 cc. of body weight) and was then injected intravenously in three divided doses at 15-minute intervals. Fifteen minutes after the end of the last injection the blood sugar was 208 mg. per 100 cc. An hour later it was 105 mg., and 2½ hours after the end of the injection it was 38 mg. The first convulsion developed 10 minutes later. Prompt recovery followed the administration of 2 cc. of 50 per cent dextrose intravenously. In the next 13 hours eleven more hypoglycemic convulsions occurred, each relieved promptly by dextrose intravenously. On the morning after the injection of alloxan the blood sugar was 190 mg. per 100 cc. and rose to 640 mg. on the 3rd day. The rabbit was kept in good condition for sixteen days, during which time the blood sugar was constantly increased, and the body weight increased to 540 gm. Persistent glycosuria accompanied the hyperglycemia, the daily dextrose excretion varying between 10 and 22 gm. Definite polydipsia and polyuria were observed, with the water intake ranging between 350 and 700 cc. and urinary excretion between 160 and 470 cc. daily. The body temperature was 104°F. before the experiment was begun and fell to 99°F. at the end of 11 hours, but subsequently returned to normal.

Repeated urinalyses failed to show albuminuria or any abnormal sediments. The blood nonprotein nitrogen varied from 36.3 to 65.0 mg. per 100 cc., whereas normal controls taken prior to the experiments ranged from 42.6 to 60.0 mg.

Bailey and Bailey consider that the initial blood sugar rise may be similar to a transitory hyperglycemia produced in rabbits by the injection of a number of substances and therefore not of great significance.

The cause of the prolonged yet limited period—twelve to twenty-four hours—of hypoglycemia that follows the injection of alloxan is at the present time debatable. Dunn, Sheehan and McLetchie¹ suggest that it may result from a primary stimulation of the islet cells. Another possible explanation is that necrosis of the islets releases a large amount of insulin.

* * *

In a second article, Dunn, Kirkpatrick, McLetchie and Telfer⁸ point out that selective necrosis of the islands of Langerhans in the pancreas has rarely been described in human beings. They cite Pettavel,⁹ who in 1912 and again in 1914 observed it in a case of hyperthyroidism associated with alimentary glycosuria. Fischer¹⁰ in 1915 noted necrosis in a child of six and a half years with severe and rapidly fatal diabetes, and cites Heiberg¹¹ as considering this lesion to represent the commencing defect that is commonly noted in diabetes. Dunn et al. reaffirmed their previous findings of necrosis in the islands of Langerhans in rabbits injected with alloxan. The acinar tissue of the pancreas remained in all cases histologically normal, even at the edge of totally necrosed islets. They cite only negligible changes as having been observed in the adrenal, thymus, thyroid and pituitary glands. In the kidneys the changes were fairly extensive, with necrosis of the proximal and sometimes of the distal convoluted tubules. The renal lesions they considered as probably due to concentration of the toxic agent in the tubules during the process of excretion, but whether this was caused by alloxan or a degradation product of the same was unknown. At times renal changes were minimal when the islet lesion was fully developed.

Fatal doses of alloxan in rabbits usually varied between 200 and 300 mg. per kilogram of body weight, the injections sometimes being divided over periods of a half to six hours. Three hundred milligrams invariably caused necrosis of the islands, although some animals survived.

Styryl-quinoline No. 90 is the only other chemical known to cause islet necrosis. The authors tried the effect of oxalic acid, uranium, guanidine and uric acid, with no comparable lesions resulting. They also tried glucose in solutions as strong as 25 per cent.

Alloxan produced similar lesions in rats and mice. Permanent glycosuria and many features of the diabetic state were recognized in 5 of 8 albino rats injected. The glycosuria could be controlled by insulin.

Death of the islet cells is the chief factor following injection of alloxan. No island remains unscathed, and in some islands apparently no cells survive.

Any living cells are at the periphery, where they may share the blood supply of acinar tissue.

* * *

Subsequently Dunn and McLetchie¹² recorded their investigation of alloxan diabetes in the rat. With doses of 300 to 400 mg. per kilogram of body weight some acute damage of the islands of Langerhans was produced, occasionally with necrosis in the renal tubules. Glycosuria was observed with almost all the symptoms of diabetes in certain of the rats, although 1 rat appeared to be recovering after two months. The glycosuria was controllable with insulin. In these rats the protoplasm of the islets was eosinophilic and hyaline, with pyknotic nuclei. In two islands there was a peripheral layer of large cells free from necrosis, which the authors thought were alpha cells, the beta cells being the cells chiefly affected. Mitoses were rare. They describe an acute effect of alloxan as follows:

No. 11 died, cold and drowsy, at 48 hours; there was no glycosuria. The changes in the islets were as in No. 9 but more severe, with more necrotic debris and more cells of doubtful viability; while obviously live cells were fewer. There were, in addition, very pronounced lesions in the small ducts in this pancreas, comprising dilatation and accumulation of wax-like eosinophil masses with leucocyte infiltration in the walls and in the interstitial septa; this lesion could be interpreted as an early pancreatitis.

They also noted that the general appearance of the islands suggested reparative changes, but they saw "none of the more characteristic islet changes described in the human disease—sclerosis or hyalinisation of islets or hydropic changes in their cells."

* * *

An intraperitoneal injection of 200 mg. of alloxan per kilogram of body weight was found to be almost invariably effective in producing diabetes by Gomori and Goldner¹³ when given to 40 rats. Of the 27 animals studied in detail, only 4 were resistant to alloxan. All the others showed hyperglycemia and glycosuria. Ketonuria was observed from the third day on and was present on subsequent days in all animals that had a blood sugar level above 300 mg. Some of the animals had a pink urine on the first day after the injection. In rats killed at the end of twenty hours, an overwhelming majority of the beta cells were greatly shrunken. In some cases the cell cords either had disintegrated into individual cells or had coalesced into an almost homogeneous debris. On the second day these changes were more accentuated, and the beta cells had started to lose the typical staining of their granules. On the fourth and fifth days only an occasional beta cell could be seen. At the same time, agranular cells of an unidentifiable type appeared in large numbers and filled the areas previously occupied by the necrotic beta cells. At the periphery, the alpha cells had proliferated considerably. By the fifth and sixth days the islets were entirely free from debris and with the routine hematoxylin-eosin stain looked practically normal.

Special stains, however, showed that they consisted of agranular and alpha cells only, beta cells being completely absent. No vacuolation of the islet cells was recognized at any stage. Mitoses were extremely rare, and the acinar parenchyma showed no change. The liver contained very little glycogen after the second day but was otherwise normal, except in 2 animals in which focal necroses were observed. The kidneys showed nothing of importance except that, from the fourth day on, deposition of glycogen in Henle's loops was quite frequently observed.

Five "hooded rats" were resistant to alloxan, possibly owing, as the authors suggest, to the exceptionally large amount of islet tissue that this strain possesses.

The histologic changes of the pancreas obtained by a single intraperitoneal injection appeared similar to those obtained by Dunn, Sheehan and McLetchie¹ with repeated subcutaneous injections of alloxan.

* * *

Goldner and Gomori¹⁴ have extended their observations on alloxan diabetes in dogs. According to the dosage of alloxan administered varying changes occurred, and they divide their experiments into four groups.

Group 1. Alloxan, above 100 mg. per kilogram. Dogs receiving this dosage died within eight hours in sudden convulsive attacks. Microscopic examination showed no changes in the islands. Although in one animal the glycosuria fell to 48 mg., death was not attributed either to hypoglycemia or to kidney damage.

Group 2. Alloxan, 75 to 100 mg. per kilogram. These animals were hypoglycemic, then hyperglycemic, and presented what the experimenters considered to be a uremic syndrome. They died in four to seven days, gradually becoming drowsy and then semicomatose, without convulsions but developing oliguria and eventually anuria. The hyperglycemia in 1 case reached 800 mg. per 100 cc. There was also a steady rise in nonprotein nitrogen, attaining in 1 case 275 mg. per 100 cc. In only 1 case was albuminuria noted. No ketonuria was found. Microscopically the absence of granules in the beta cells was apparent, but the alpha cells were unchanged. There was no vacuolation in the cells of the islands or ducts. Extensive necrosis of the convoluted tubules was apparent, with glycogen in Henle's loops. The liver was normal.

Group 3. Alloxan, 50 to 75 mg. per kilogram. Dogs receiving this dosage developed diabetic symptoms and signs — polydipsia, polyuria, loss of weight, hyperglycemia and glycosuria. There was no ketonuria, albuminuria or increase in nonprotein nitrogen, but there was an increase in lipemia and the respiratory quotient fell to about 65. Pathological examination revealed small islands, no normal beta cells and no hydropic degeneration of the beta cells. There were no mitoses of the islet cells. Extreme vacuolation of the epithelium of all intralobular ducts occurred in the later stages of the disease. The kidneys were normal save for the presence of glycogen. There was fatty infiltration of the liver, with 31 per cent lipids, and the phosphatase reaction was increased.

Group 4. Alloxan, 25 mg. per kilogram. This dose was ineffective.

In summary, intravenous administration of alloxan to dogs in a single dose exceeding 100 mg. per kilogram of body weight caused death of the animals within a few hours. A dose of between 75 and 100 mg. produced a diabetic uremic syndrome of which the animals died within a week. A dose of 50 to 75 mg. produced typical diabetes without renal lesions, and these animals were kept alive for weeks. The

main histologic features were a disappearance of beta cells from the islets, profound vacuolation of the epithelium of the pancreatic duct and fatty changes of the liver. Doses of 25 mg. were without effect.

* * *

In studies on the insulin tolerance, Dragstedt, Afsen and Smith¹⁵ observed that more insulin appeared to be required to establish the control of glycosuria in dogs with certain types of partial pancreatectomy than in totally depancreatized dogs. Likewise, in 2 dogs made diabetic by the intravenous injection of alloxan, the requirement of insulin was 32 and 36 units of regular insulin daily, which Goldner and Gomori consider somewhat greater than that for depancreatized animals at the same period.

* * *

In their second article, entitled "Alloxan Diabetes with Diabetic Complications," Bailey and Bailey¹⁶ have advanced materially the knowledge of the action of alloxan in rabbits and rats and have shown clearly how closely the disease in the experimental animal approaches that in human subjects. They report that cataracts were found in all such rabbits within four to six weeks after the diabetes was induced. These were chiefly subcapsular and were more advanced in the posterior cortex, where they appeared earlier than in the anterior cortex of the lens. Like previous workers, these authors found the histologic changes in the animals to be confined to the islands of Langerhans, save for mild tubular degeneration of the kidneys and slight fatty metamorphosis of the liver.

A gradual onset of diabetes, thus more closely resembling the usual variety found in human beings, was obtained by the Baileys when alloxan in doses of 40 mg. per kilogram of body weight was given to rabbits in repeated intravenous injections. In 2 such rabbits after the seventh and the thirteenth injection, respectively, the blood sugars were over 200 mg. per 100 cc. and were accompanied by glycosuria, and the islet cells showed a variety of lesions, described as follows:

Some cells, especially those at the periphery of the islets, appeared essentially normal. In other cells, the nuclei were well preserved, as was the ground substance of the cytoplasm, but the granules were not present. Numerous cells presented a clear-cut picture of hydropic degeneration, which has been shown to be a reversible change. Among the cells with hydropic degeneration, there were occasional cells with large clear vacuoles but with the nuclei staining in a homogeneous manner and without chromatic pattern; this appears to be an irreversible change because of the nuclear damage. Mitosis was seen in several islet cells but in no instance was there more than one mitosis in an islet. This complex picture of normal cells, slightly injured cells, cells with hydropic degeneration, and cells with other changes seems best interpreted as a complex response to an injurious agent with some cells capable of survival if the agent is removed, while others are dead and are being replaced by mitotic division of surviving islet cells.

In 1 rabbit, after cessation of injections, the diabetes seemed to disappear, but careful studies over

a period of two and a half months disclosed its persistence. Twenty milligrams of alloxan per kilogram, even if repeated three times a week for seventy-one days, did not produce diabetes, but 40 mg. per kilogram did so if repeated.

Alloxan diabetes was most readily produced in rats by subcutaneous injection. In 2 rats diabetic cataracts developed after two or three months. Diabetic acidosis was rare, but did occur with typical symptoms. In one rat, recovery took place with the help of insulin, but in another, diabetic coma developed, along with extreme polydipsia, a dry tongue, Kussmaul respiration and drowsiness, which finally led to unconsciousness and death.

The rats that received the alloxan intraperitoneally or intravenously instead of subcutaneously showed extensive necrosis of the liver and severe lesions of the kidney, predominantly tubular in type. The rat that received alloxan subcutaneously and developed diabetic coma did not have liver necrosis. Thus it was concluded that the subcutaneous injection of alloxan in doses of 200 mg. per kilogram was a feasible method for producing diabetes in the rat.

* * *

Hughes, Ware and Young¹⁷ found islet-cell changes within five minutes of the subcutaneous ingestion of alloxan into rats. The large islets were not only the first damaged but likewise showed the greatest injury. The initial hyperglycemia ending in hypoglycemia that follows the injection of alloxan was reproduced in rabbits by the injection of adrenalin and protamine zinc insulin equivalent to the amount of insulin known to be present in the pancreas of a normal rabbit—namely, 10 units per kilogram of body weight. A valuable editorial in the same issue of the *Lancet*¹⁸ recalls that Liebig, Lang and others claimed that alloxan could be found in animal secretions and that if alloxan is a constituent of mucoproteins its physiologic significance may be much greater than was ever thought.

INCIDENCE OF DIABETES

Blotner, Hyde and Kingsley¹⁹ report studies in diabetes mellitus and transient glycosuria in 45,650 consecutive selectees and volunteers, aged from eighteen to forty-five years, in the Boston Armed Forces Induction Station. The incidence of diabetes that they found is approximately three to four times that of a nearly similar age group in 1935-1936, ascertained through a house-to-house canvass by the United States Public Health Service. This recent investigation of the incidence of diabetes deserves most careful attention, because the diagnostic methods were sound. Not only was the urine examined, but if sugar was found it was tested before and after lunch on the same day. If the urine repeatedly showed sugar and there was not a verified history of diabetes, the men were sent to an Army hospital for

a 100-gm. glucose-tolerance test carried out after the subjects had fasted all night. Diabetes was diagnosed when the blood-sugar concentration reached a level of 180 mg. per 100 cc., and some or all of the specimens of urine contained varying amounts of sugar. The cases of mild diabetes usually showed normal fasting blood-sugar levels, rising to 200 or 220 mg. per 100 cc. and then falling in two hours to 150 mg. and in three hours to 100 to 125 mg.; those moderately severe presented a fasting level above 140 mg. per 100 cc., with or without glycosuria in the fasting specimen, but the blood sugar reached 275 mg. per 100 cc. and dropped to about 200 mg. in three hours. The severe cases showed a fasting level of about 275 mg., with considerable amounts of sugar in the urine; after the ingestion of glucose the blood sugar rose to about 475 mg. in one hour and dropped only slightly in three hours.

Transient glycosuria was diagnosed in the men who had varying amounts of sugar in the first specimen of urine tested but negative reactions on subsequent days. If, as the writers say, sugar-tolerance tests had been done on all these cases, it is probable that a number of additional cases of diabetes mellitus would have been discovered.

The cases of diabetes mellitus numbered 208, those of transient glycosuria 126, and those of renal glycosuria, as interpreted by the authors, 33.

The average age of the diabetic patients was 34.4 years and of the men with transient glycosuria 27.5 years. The control group averaged 27.5 years. The diabetic patients were on the average (158 pounds) about 18 pounds above the weights of 1000 consecutive selectees (140 pounds) and were of normal average height. Tuberculosis occurred in about the same proportion of the diabetic patients as of the nondiabetic subjects. A diabetic heredity was about six times as frequent in the diabetic patients—32 per cent—as in the nondiabetic subjects used for control—5.2 per cent. No significant variation was noted in the prevalence of diabetes in selectees from communities of different socioeconomic levels or in the prevalence in areas classified by welfare relief paid per capita. The incidence in dense urban areas was 0.8 per cent, as contrasted with 0.4 per cent in the least populated area, and this the writers attribute to the greater proportion of Jews and Irish in the former. Occupation proved to be of little significance. There were twice as many Jews in the diabetic group as in the control group, and nearly half again as many Irish in the diabetic group as in the control group.

I attach great importance to these studies. I have always believed diabetes to be commoner than statistics have revealed. To a slight degree I can confirm the accuracy of diagnosis as performed at various Army hospitals, because many men rejected by the Army, and by the Navy, as well, have later been seen by me for diagnosis and treatment. Of all those re-examined, a difference in diagnosis has probably

not occurred in more than 5 cases. The outstanding patient was one who was ill with a respiratory infection when he took the induction test and was rated a diabetic patient, but later when re-examined he was accepted. The other cases were apparently borderline ones, with the blood sugar varying between just above and just below the diagnostic level. The usual Army diagnosis was overwhelmingly correct.

Subsequent and similar studies may well change the entire conception of the incidence of diabetes in the United States, so far reaching are the implications arising from the studies of Blotner, Hyde and Kingsley.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., Editor*

BENJAMIN CASTLEMAN, M.D., Acting Editor

EDITH E. PARRIS, Assistant Editor

CASE 30141

PRESENTATION OF CASE

First admission. A forty-two-year-old yardman entered the hospital because of upper abdominal pain.

The patient had been in excellent health until six months before admission, when he noted episodes of indigestion, especially after meals; they were relieved by soda. These increased in frequency and severity, and about six weeks before entry he developed attacks of pain in the "pit of the stomach." Two weeks later he began to vomit four or five times daily, without any definite relation to meals. The pain increased in severity and became almost continuous. He lost 20 pounds in weight in about one month.

Physical examination showed a well-developed, somewhat emaciated man. The heart and lungs were normal. There was slight tenderness over an orange-sized mass situated in the left upper quadrant.

*On leave of absence.

The blood pressure was 108 systolic, 95 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood showed a red-cell count of 4,700,000, with 90 per cent hemoglobin. The white-cell count was 7000. The urine was negative. A blood Hinton test was negative. A gastrointestinal series showed the entire stomach to be rigid. There was marked thickening of the wall. The mucosal pattern was absent.

Abdominal exploration on the seventh day showed a large carcinoma of the stomach with some small hard nodules in the gastrocolic ligament. The stomach was not fixed. The spleen was twice the normal size. A total gastrectomy with esophagojejunostomy and splenectomy was performed. A portion of the transverse colon was removed, and the middle colic vessels were sacrificed. It was impossible to close the defect in the mesocolon. Through a McBurney incision a complementary cecostomy was then performed. The pathological diagnosis was scirrhus carcinoma with metastases to the regional and celiac lymph nodes.

The patient withstood the operation well and had an essentially uneventful postoperative course. The cecostomy tube was removed and he was discharged on the twentieth postoperative day.

Second admission (six days later). Following discharge the patient did well except for occasional gas pains. About noon on the day of admission he developed an increasingly severe lower abdominal pain. The pain was steady in character and spread to the upper abdomen and down the left side. Five hours later, following a light supper, the pain became almost unbearable. There was no vomiting and only slight nausea. The stools, which had been

normal, were said to have become extremely hard and painful on that day. He had no chills, fever or sweats.

Physical examination showed a slightly distended abdomen. There was generalized voluntary spasm, maximal in the left upper quadrant. No masses were palpable. Peristalsis was normal in pitch but active. Rectal examination was negative.

The temperature was 99.2°F., the pulse 92, and the respirations 20.

Examination of the blood showed a white-cell count of 14,700.

X-ray films of the abdomen showed no free air under the diaphragm. The right half of the diaphragm was slightly elevated. There was an air-filled loop of small bowel in the left upper quadrant that showed a fluid level on standing and was apparently somewhat dilated. No other dilated loops were present. There were scattered areas of gas throughout the abdomen: moderate amounts in the large intestine, and possibly some in the small. The appearance of the abdomen was suggestive of fluid.

The patient was given 500 cc. of blood, as well as plasma and intravenous fluids. A Miller-Abbott tube was passed. Exploratory laparotomy under spinal anesthesia showed a moderate amount of dusky fluid and many white carcinomatous nodules. There were no dilated loops of bowel, no evidence of obstruction, and no leakage around the anastomoses.

Postoperatively the temperature ranged between 99.6 and 100.5°F. The abdominal distention increased. There was no audible peristalsis. The patient complained of pain in the testes and penis. There was considerable vomiting, and occasional hiccoughs. He was given additional intravenous fluids and transfusions. On the third postoperative day he developed jaundice. On the evening of the fifth postoperative day he suddenly went into shock, with profuse sweating and dyspnea. The blood pressure was unobtainable. He was quite distended, and peristalsis could not be heard. He died ten hours later.

DIFFERENTIAL DIAGNOSIS

DR. FRANCIS D. MOORE: Just before the second operation x-ray films were taken. May we see them now?

DR. LAURENCE L. ROBBINS: In this film, taken in the upright position, there are fluid levels and slightly dilated loops of small bowel. The descending colon is visible down to the sigmoid. These loops of small bowel are where the stomach and spleen used to be.

DR. MOORE: Usually in these conferences one is given a history and a physical examination; the patient goes to operation, and one tries to determine the diagnosis. Here we have a patient with two histories, two physical examinations and two

operations, and still we do not know the diagnosis.

Everybody will agree that the fundamental lesion was scirrhus carcinoma of the stomach, and there is no use in spending more time on it. The problem is, What was the nature of the postoperative complication that was fatal?

As we go back over the history we find that at the first operation it was impossible to close the defect in the mesocolon. The esophagus was anastomosed to the jejunum. The duodenum was turned in almost unquestionably, and an enteroenterostomy done — it is not mentioned, but it is virtually routine in this type of anastomosis. The mesocolon coming across in front of the duodenum was brought around anteriorly and the transverse colon had to be cut as part of the operation, a portion being resected including the middle colic vessels. So the patient had another suture line there. He also had a cecostomy.

As to the defect that was not closed — I think that is more or less of a red herring. Following a total gastrectomy, when the jejunum is brought up it is unusual to be able to close the transverse mesocolon. If one did close it around two loops of small bowel, one might get into trouble from the closure because it would tend to cicatrize around the bowel. I should like to know what Dr. Sweet has to say about that. In my experience it is extremely unusual to close the mesotransverse colon in this procedure. Whether that is significant or not I do not know, although there are factors later that suggest that something was going on at the root of the mesentery.

The patient was discharged on the twentieth postoperative day. With such an extensive operation that must mean he had an extremely uneventful convalescence. He went home and for six days had occasional "gas pains." If we interpret these pains to mean the smooth-muscle peristaltic cramps of small bowel trying to put a fecal stream through around an obstruction, we must admit that there was something wrong. This is infrequent with gastrectomy of any sort, because the bowel distended to the esophagojejunostomy is not tampered with. It is out of the field of operation, and to have symptoms of small-bowel obstruction lower down is unusual.

On the day of the second admission the patient developed severe pain in the lower abdomen, which spread upward and down the left side. Possibly one should lay stress on the fact that it started below the umbilicus; but it apparently became diffuse and fits in with the concept that he was having smooth-muscle pain in the small bowel. Five hours later he ate supper, after which he became much sicker, which suggests that the obstruction, if it had one, was high up so that eating a meal immediately filled the obstructed loop. When he was admitted he had a slightly distended abdomen and mild spasm, which are compatible with obstruction.

There was no free air, which is comforting. At least there was no perforation.

Then we come to the x-ray examination, which showed air in the large bowel. One might argue that that is evidence against small-bowel obstruction, but it is worth pointing out that with early, high small-bowel obstruction a patient may maintain gas and feces in the large bowel for twenty-four hours before he expels them. Thus, in the first twelve, eighteen or twenty-four hours of high small-bowel obstruction it is possible to find dilated loops as well as gas and feces in the large bowel. Whether the loops in that x-ray film are dilated is open to argument. The haustral markings are coarse, which is characteristic of jejunum rather than of ileum. The finding, however, of frank fluid levels in this area in the vertical position strongly suggests that they are pathologic.

A Miller-Abbott tube was passed. That is interesting because a Miller-Abbott tube could have gone two places in this man: down the esophagus and into the afferent loop or down the esophagus and into the efferent loop, depending totally on the mechanism of the anastomosis. The chances are that it went into the efferent loop, and I think that that is important.

Exploratory laparotomy under spinal anesthesia then showed dusky fluid and white carcinomatous nodules. That is discouraging but probably did not have a great deal to do with what killed him. The dusky fluid in the face of an otherwise negative laparotomy is still compatible with my working diagnosis, because one of the first things that happens in the peritoneal cavity in small-bowel obstruction is the transudation of fluid, and a dusky brown color is characteristic. When they operated on this man, if he had been obstructed, his obstruction had been reduced, or if he had had an internal hernia, it had been reduced, and all they found were the leftovers of the obstruction—nothing that they could remedy. There is no comment on where the Miller-Abbott tube was or how far it went down, but since the patient had no pylorus I assume that it went down a foot or two into the upper jejunum.

DR. GORDON A. DONALDSON: We did not follow it.

DR. MOORE: I think that the findings at operation were compatible with reduced small-bowel obstruction. There was no leakage around the anastomosis. The fact that there was no audible peristalsis postoperatively is of no significance because of the short period of time postoperatively. One would not expect normal peristalsis to get going so soon.

The pain in the testes and penis is hard to interpret, but the lymph, blood and nerve supplies of the testis originate in the somatome that is associated with the kidney. The spermatic arteries come from there, and so it is conceivable that something was going on at the root of the mesentery: tumor, lymphadenitis, torsion or decreased blood supply.

There was considerable vomiting. That is certainly an unusual thing in a person with no stomach in whom a Miller-Abbott tube had been passed. One would not expect vomiting. In the first place it is difficult to visualize because fluid has to run back up from the anastomosis in order for the patient to vomit. That is evidence that there might have been obstruction of a loop into which the Miller-Abbott tube had not passed. This could have been the afferent loop or the loop running from the duodenal closure to the anastomosis.

On the third day the patient developed jaundice. That is an interesting finding. Of course it could have been due to a lot of factors. He could have had carcinoma in the liver sufficiently extensive to give jaundice, or carcinoma around the extrahepatic biliary tree giving obstructive jaundice. But, on the other hand, he became jaundiced with the acute episode and I think it is fair to assume that all of it was part of the same process. Where could he have obstructed a loop of bowel that would produce jaundice? The answer is, The afferent loop. If this loop was obstructed, it is tantamount to obstruction of the common duct, which comes down and enters the afferent loop at the papilla. If that was obstructed, he could not drain bile, would get retrograde pressure back through the papilla and might get jaundice.

On the fifth day he went into shock, with profuse sweating and dyspnea. There are two things that could produce death that rapidly in this man. One is massive intraperitoneal hemorrhage or, as a matter of fact, hemorrhage anywhere. I say "intraperitoneal" because he did not bleed externally. Did he have that? He could have had it, but I do not believe that that is what he had. I think that something perforated and that he died of the shock of a tremendously overwhelming chemical peritonitis. The perforation of a suture line in a portion of bowel that is obstructed below is a much more dramatic and much more shock-producing event than any other form of perforated viscus of which I know. A perforated peptic ulcer classically is supposed to produce shock. Yet of the patients that come to this hospital for perforated peptic ulcer only a very few are in shock. But a patient who is obstructed, "blows out" a suture line and floods his peritoneal cavity with a tremendous amount of intestinal contents, goes into shock and dies rapidly if there is nothing to wall it off.

Can a loop of bowel become obstructed and perforate in this short period of time? It was five days at the most, since we know that the patient did not have obstruction at the second operation. If there were nothing in the bowel to weaken it, such as a suture line or a tumor, I think that the answer is. No. A loop of small bowel may be strangulated for some time before it perforates, and during that period it usually becomes adherent to adjacent loops and may never have free peritoneal perforation.

So that fits in with the general concept that there was obstruction of the afferent loop, which had not been drained by the Miller-Abbott tube, had been reduced at the first operation, had become re-obstructed, had produced jaundice and had eventually blown out one of the three suture lines.

What are the other possibilities? Massive hemorrhage? I do not believe so. Could he have perforated or blown out the suture line in the transverse colon? Yes, but I do not believe that he did. Did he have a completely separate and independent lesion — another carcinoma — that obstructed? Possibly, but there is no evidence for it. Someone may say that thirty-one days after the first operation is too long to have blown out a suture line. It is true that the usual time is seven to ten days, but this man did not have a suture line alone — he had a suture line plus obstruction below it, and the suture line gave out simply because it was the weakest point in the system. Why did he have obstruction of the proximal loop? There are two possibilities. One is that the bowel became kinked at one of the two anastomoses. The other, which is the more likely, is that the patient had a long afferent loop that became herniated into the left upper quadrant behind the efferent loop. That is my diagnosis. He had an obstructed afferent loop — possibly a hernia into the left upper quadrant — that had been reduced at the time of the second operation, became obstructed again and finally blew out the duodenal suture line.

DR. RICHARD H. SWEET: I should like to suggest that the lethal episode that this man suffered was the result of acute pancreatitis. Furthermore, at the second operation it is possible that he might have had an unrecognized pancreatitis.

The other point that I should like to raise is that if Dr. Arthur W. Allen operated on this patient it is unlikely that the patient had a long proximal loop, since that is contrary to his technical method in this type of operation.

DR. MOORE: If the patient had a short proximal loop it would be unlikely that he had a hernia of it. He could, however, obstruct the afferent loop by a kink at the anastomosis.

DR. SWEET: Dr. Allen told me once that he made a great point of placing the enteroenterostomy in this operation as close as possible to the ligament of Treitz.

DR. MOORE: Do you agree that the closure of the mesocolon is unusual?

DR. SWEET: It is in my own practice. I never do it after total gastrectomy.

DR. MOORE: It was possibly a herniation of small bowel independent of the anastomosis, through the rent in the mesocolon; and yet I do not think that is what he had because, as Dr. Sweet has pointed out, it is unusual to close such a rent.

DR. SWEET: I should like to qualify my statement, because this is not strictly a surgical audience.

We do close the rent in the mesocolon in subtotal gastrectomies, but we do not do it in total gastrectomies. Closure of the mesocolon around the loop jejunum is carried out by some surgeons, I am sure, but my own feeling is that it is better not to, or at least that it is unnecessary.

DR. CHESTER M. JONES: I should like to raise question about jaundice caused by obstruction the proximal jejunum or end of the duodenal loop. It must be an unusual occurrence.

DR. MOORE: I saw one patient without biliary tract disease but with an obstructed afferent loop after a subtotal gastrectomy who developed jaundice of a minor order. How much jaundice was there in this patient?

DR. BENJAMIN CASTLEMAN: It was reported mild on the ward, but it must have gradually increased because at autopsy there was significant jaundice.

DR. MOORE: He could have had biliary tract disease entirely independent of the acute episode of biliary tract disease with obstruction of the duodenum and perforation of the gall bladder.

DR. CASTLEMAN: Will you elaborate on the second operation, Dr. Donaldson?

DR. DONALDSON: We were reluctant to operate and waited about twelve hours. This we would have done if the patient had not had the operation four weeks previously and undoubtedly present a good many adhesions. Moreover, an x-ray film was taken, which apparently was not reported. Swallow of barium after the first operation showed air-filled loops of bowel in the left upper quadrant. Another reason why we delayed was that the type of pain was unusual. It was lower abdominal pain.

After waiting for twelve hours, however, with a rise in the white-cell count and increased tenderness, we thought that we had to do an exploration. We were quite disturbed to find a small bowel that showed no evidence of obstruction. We were able to put a hand behind the mesocolon and feel the proximal and distal loops, which were not dilated. He did have diffuse carcinomatosis.

DR. MOORE: Did you feel the gall bladder?

DR. DONALDSON: The right upper quadrant was filled with loops of adherent jejunum.

CLINICAL DIAGNOSES

Scirrhus carcinoma of stomach, with metastases to regional lymph nodes and peritoneum.
Operations: total gastrectomy and splenectomy.
Pulmonary embolus?
Acute generalized peritonitis?

DR. MOORE'S DIAGNOSES

Scirrhus carcinoma of stomach, with metastases to regional lymph nodes and peritoneum.
Operations: total gastrectomy and splenectomy.
Small-bowel obstruction.
Rupture of duodenal suture line.
Acute generalized peritonitis.

ANATOMICAL DIAGNOSES

(Scirrhus carcinoma of stomach with metastases to regional lymph nodes.)

Carcinomatous metastases to peritoncum.

Operations: total gastrectomy and splenectomy.

Thrombosis of splenic, portal and superior mesenteric veins.

Mesenteric venous thrombosis, recent.

Infarction of small intestine.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The autopsy on this man showed, in addition to a moderately infected abdomen, a loop of small bowel about 100 cm. long that had all the characteristics of infarction and early gangrene. This loop was somewhat bound down and when dissected was located about 100 cm. from the ligament of Treitz. Examination of the mesentery of that loop showed that all the veins were filled with recent thrombi, probably three or four days old. Certainly this loop of bowel was not involved at the time of exploration or it would have been observed. The splenic vein was also completely thrombosed, but this was an old thrombosis — apparently resulting from splenectomy at the time of the first operation. The splenic-vein thrombus extended for a short distance into both the portal and superior mesenteric veins. Within the liver many of the radicles of the portal vein were likewise occluded by thrombi of all ages, which probably accounted for the jaundice. It is possible that during the second operation, in manipulating to try to find the area of obstruction, a small thrombus was broken off, which entered the vein returning blood from the involved loops and caused retrograde thrombosis. Of course, that would have been against the flow of blood, but such a stream may be sluggish, especially in the presence of peritoneal irritation from metastases and infection.

We have seen two other cases in which, following splenectomy associated with a gastrectomy, small thrombi were found in the portal radicles of the liver and in the splenic vein. Perhaps that occurs oftener than we suppose, and the patient gets away with it. In one of these cases the patient died of peritonitis following a rupture of the anastomosis. Perhaps removing the spleen along with a gastrectomy is not without danger. Have you any comment, Dr. Sweet?

DR. SWEET: I have recently given that a lot of thought. I wonder if the thrombosis in the tied-off splenic vein may not be the cause of the so-called "postsplenectomy fever," which often follows splenectomies, especially those performed in cases of Banti's syndrome, whatever that may be. This is a long-lasting fever, which gradually subsides after a period of weeks.

DR. CASTLEMAN: The patient had fever following the first operation but it soon disappeared.

DR. SWEET: This is not at all clear. You have not proved to my satisfaction that the bowel lesion that you discovered existed before Dr. Donaldson's operation, or that it caused pain in the lower abdomen.

DR. CASTLEMAN: Perhaps not at that operation; the gangrene of the bowel was a recent event.

DR. SWEET: Probably following Dr. Donaldson's operation. What was the cause of the symptoms before?

DR. CASTLEMAN: Probably the thrombosis of the splenic vein.

DR. SWEET: Then I should like to ask Dr. Jones if pain from such a thrombosis would be referred to the lower abdomen. I doubt it.

DR. JONES: This patient's pain sounds much more like that of a pancreatitis. I should agree with Dr. Sweet that pain arising from a splenic-vein thrombosis presumably would be high in the abdomen or in the back, or in both.

DR. DONALDSON: It started in the lower abdomen but soon spread to the left upper abdomen.

DR. JONES: Did he have enough carcinomatosis to produce pain?

DR. CASTLEMAN: No.

DR. SWEET: The localization of pain is so important in the making of a diagnosis that in cases of this sort we ought to have it clearly in mind that it often occurs in the upper abdomen.

DR. CASTLEMAN: The final localization of the patient's pain in the left upper quadrant is consistent with thrombosis of the splenic vein.

CASE 30142

PRESENTATION OF CASE

A twenty-seven-year-old Norwegian seaman entered the hospital because of increasing pain in the right hip.

The patient was in perfect health until about five years before admission, when he developed a painful right knee. He was seen by a physician, who told him that his hip was the involved joint. He was treated by bed rest, with great improvement. The pain apparently disappeared until two years before entry when, after being kicked in the thigh, he began to notice pain and limitation of motion in the right hip. He was hospitalized for eight months, after which he was able to return to work. Subsequently, however, the pain increased in severity and there was considerable limitation of movement. He walked with a limp. No other information was available.

Physical examination showed a well-developed and well-nourished man in no distress. The heart, lungs and abdomen were normal. Hip flexion on the right was limited by pain to 90°. Internal and external rotation was limited by pain to 15°. Flexion and extension of the hip produced a grinding motion

and palpable crepitus. There was no discernible atrophy or shortening of the limb.

The blood pressure was 125 systolic, 73 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood showed a white-cell count of 6000, with 70 per cent neutrophils. The hemoglobin was 15.1 gm. per 100 cc. The urine was negative. The sedimentation rate was 12 mm. in sixty minutes. A blood Hinton test was negative.

X-ray examinations of the right hip showed a rounded area of diminished density in the acetabulum and along the superior side of the neck of

FIGURE 1. Roentgenogram of Right Hip Joint.

the right femur, with very little bone reaction (Fig. 1). The joint spaces were slightly narrowed, but the joint surfaces were intact. The head of the femur showed some flattening. In the lateral view the shaft displayed moderate atrophy and coarse trabeculation. X-ray films of the chest were negative except for adhesions to the left diaphragm.

On the third hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. JOHN REIDY: We might start by looking at the x-ray films.

DR. LAURENCE L. ROBBINS: These are the areas of rarefaction that were described, with the narrowing

of the joint and the flattening of the head. It is quite impressive, particularly in comparison with the previous case,* to see the lack of bone reaction. The decalcification in the right side of the pelvis as well as in the femur is probably on the basis of atrophy. The chest is essentially negative.

DR. REIDY: The adhesions in the chest could have been the result of an infectious process. Is there any evidence of tuberculosis?

DR. ROBBINS: There is possibly some fibrosis in the upper lobes, particularly on the left, but even that is questionable. This could be attributed to old tuberculosis, and the adhesions could be on the basis of an old pleurisy. Certainly there is no evidence of active tuberculosis.

DR. REIDY: This man was relatively young, twenty-seven years old, with quite limited hip function and considerable pain that was sufficient to force him to stop work. He had been hospitalized on several occasions over a relatively long period and the last time he had been immobile for a period of eight months before he was able to get about. On the first occasion we do not know how long he was kept in bed, but it was probably for a fairly long period.

On physical examination there was little other than limitation of motion, described as having been due mostly to pain, but probably also because of the deformity, since one factor rarely causes limitation of motion. It is unusual to see so much atrophy of the bone and none in the soft tissues of the extremities. The description in the physical examination says that he had no discernible atrophy of the thigh.

We have to rule out the possibility of an old slipped epiphysis, which I think is most unlikely since the hip was in relatively good position, although it could have slipped slightly, in that the anterior lip in this film is a little low. That could produce traumatic arthritis due to faulty mechanics of the hip joint.

Legg-Perthes's disease is a possibility, but more broadening of the head and flattening would be expected in that condition. The lesion in question shows narrowing of the joint space. In addition to the diminished density in the acetabulum there is also some evidence of destruction in the head of the femur, which could be the result of a disease process crossing the joint or just due to disuse. It could occur, however, as the result of trauma.

Gout is most unlikely. Nothing is said of an elevated blood uric acid, and the x-ray picture is, I believe, unlike it; although I have seen a case somewhat similar to this, in which a gouty nodule was removed from the capsule of the hip joint. A malignant neoplasm is also unlikely since, after five years, one would expect more destruction than we see here.

*Case records of the Massachusetts General Hospital (Case 3013) *New Eng. J. Med.* 230:409-412, 1944.

A low-grade inflammatory process, I believe, is the thing that must be considered. There is no help so far as blood count or sedimentation rate is concerned.

Osteochondritis dissecans, again the result of trauma, is a possibility, particularly in view of the fact that they mention a grinding sensation, which might mean that a portion of the acetabulum or head of the femur had been broken off into the hip joint, although the crepitus might well be accounted for by the irregularity and the defect in the acetabulum.

I believe that we should also consider xanthoma or Gaucher's disease. I have seen a case of Gaucher's disease with a lesion in the acetabulum similar to this that did not cross the joint and therefore had produced no change in the head of the femur.

In a young man of twenty-seven it is unusual to have a traumatic arthritis of this degree. I should think that he probably had a low-grade infection, since there is no evidence of anything acute, and a tuberculous lesion should be seriously considered. Tuberculosis of the acetabulum does occur but less frequently than does tuberculosis of the head. X-ray evidence of involvement of the head, with a moderate degree of atrophy and destruction, should permit us to consider tuberculosis as a thoroughly tenable diagnosis.

There is another unusual lesion that might be mentioned in this case, in view of the fact that he was a seaman. Had he done any diving?

DR. MARIUS N. SMITH-PETERSEN: In spite of the history, he was not a seaman.

DR. REIDY: If he had been a diver, caisson disease might be considered. Sometimes the vessels in the terminal portions of the bone become occluded and an aseptic necrosis results, with a picture similar to this and destruction of the joint as the lesion goes on.

To summarize, this man had a fairly extensive lesion in the hip, considerable atrophy of the bone about the hip joint, a definite area of bone destruction in the acetabulum and another area of destruction in the head of the femur, with narrowing of the joint. The fact that he improved with long periods of rest, only to have recurrences, is suggestive of a low-grade infection, and I make tuberculosis my first diagnosis rather than a neoplastic type of lesion.

DR. SMITH-PETERSEN: One cannot afford to be little the changes in the head and neck of the femur,

because there was distinct change in the architecture of the two. The changes in the epiphyseal line are perfectly consistent with several epiphyseal slips. The patient had symptoms at the age of twenty-one. At that time he was beyond the stage of a slipped epiphysis, but in skiing he must have been exposed to trauma and could have had minor slips earlier in life to which he paid little attention. After twenty-one, he had symptoms perfectly consistent with faulty architecture and at that time was in bed for six or seven months.

Our preoperative diagnosis was traumatic arthritis secondary to faulty architecture, which would account for the changes in the acetabulum. Whether it began as cystic degenerative change, we did not know. At the time of operation, on approaching the joint, the anterior acetabulum was cut through and the cut went across those areas that you see, which contained pink gelatinous material. There was some discoloration of the adjacent articular cartilage. The changes in the head were perfectly similar to the changes that one finds in malum coxae senilis, in which there are cystic areas; but that is not what these areas represented. To call them cysts is hardly correct. They were degenerative fatty areas that when squeezed oozed material similar to olive oil. There was villus change in the inferior compartment but the villi were not the ordinary type. The joint did not have the appearance of a joint that was or had been infected, nor did it resemble tuberculosis in any way, shape or manner. The postoperative diagnosis was traumatic arthritis, and a cup arthroplasty was done.

CLINICAL DIAGNOSIS

Traumatic arthritis.

DR. REIDY'S DIAGNOSIS

Tuberculosis of acetabulum, head of femur and hip joint.

ANATOMICAL DIAGNOSIS

Tuberculosis of hip.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: Microscopic examination of the synovial lining of the joint, as well as that of the bone of the head of the femur, showed tuberculosis.

HOSPITALIZATION FOR ACUTE COMMUNICABLE DISEASES

THERE are many good reasons for reconsidering the role of special contagious-disease hospitals. In recent years a definite change in attitude toward certain diseases has occurred, and they have been taken out of the class of those that are considered suitable for isolation in special hospitals. An example of immediate interest is meningococcal meningitis. In the past, cases of this disease have been considered especially suitable for care in isolation hospitals but now they are being treated in the wards of general hospitals without difficulty. The problem of isolation and quarantine in cases of scarlet fever has been considered in a recent edi-

torial in the *Journal*.¹ It is quite incongruous in the light of present-day understanding of streptococcal infections to consider scarlet fever as the only one of a group of hemolytic streptococcus diseases that requires isolation in special contagious-disease hospitals, while patients with tonsillitis or septic wound infections are treated in the open wards or in single rooms of general hospitals. Smallpox may be considered as an extreme example. "even with this disease the facts that . . . tion against it is practically universal and that the immunity of the hospital personnel can be maintained by frequent revaccination make it perfectly feasible to treat cases of this disease in single rooms of general hospitals.

General hospitals are, willingly or otherwise, treating cases of all sorts of communicable diseases at the present time. Many patients are admitted before the correct diagnosis is made and when they are presumably at the height of their contagiousness and when the possibility of communicable disease is entertained, the staff of the hospital must be prepared to use proper technic to avoid transfer of infection to themselves and to others. This makes quite essential for the entire staff to be acquainted with the technics that limit the spread of contagious diseases.

The diagnosis and care of open cases of tuberculosis, although different in many respects from those of other acute communicable diseases, present some problems along the same line. The hospitals for the care of such cases are crowded, and even when beds in such institutions are available, many patients are loath to take advantage of their facilities. General hospitals, particularly large municipal hospitals, are constantly called on to receive such patients and to hold them for long periods, pending their final placement in suitable institutions. During this time, the open cases of tuberculosis are in many ways similar in their contagiousness to other cases of the more acute infectious diseases. Arrangements for their management should be adequate to minimize the spread of disease among the hospital contacts, and such arrangements are nowise different from those necessary for the care of patients with other communicable diseases.

Another factor to be taken into account, particularly in this part of the country, is the steady increase in the burdens that the general hospitals are carrying. All physicians in large cities are constantly troubled with the inability to obtain hospital facilities for those among their patients who require care that cannot be given in the home. The overcrowding of these hospitals is due, in large measure, to the increase in popularity of the agencies that provide hospitalization insurance. In the future it is to be expected that hospital insurance will become more rather than less popular and that the burden on the general hospitals will consequently increase.

The specialized hospitals for contagious diseases, on the other hand, are not being used to capacity. Even during epidemics the use of their facilities is only temporary. The staffs of such hospitals are necessarily large, and a good part of the staff must be maintained even when this is not warranted by the number of cases. Furthermore, because of the wide fluctuations in use, their facilities are often permitted to deteriorate, and the aid of modern equipment and treatment, which is available in general hospitals, is often denied to patients.

The present problem of the shortage of nurses may provide a good excuse for the immediate consideration of this important problem. Contagious-disease hospitals require a relatively greater number of nurses per patient than do general hospitals and much of the time a large percentage of these nurses are not working to capacity, general hospitals, on the other hand, are much understaffed and their nurses are greatly overworked.

The objection that provisions must be made for the emergencies incident to epidemics does not provide an argument for the maintenance of special contagious-disease hospitals. General hospitals should be able to expand their facilities for the emergencies provided by disasters, and epidemics may well be classed in a group with other disasters. The reorientation of existent communicable-disease hospitals to serve within the framework of the general hospitals, although it might not entirely alleviate the nursing and bed situation, would undoubtedly be of some help. The views of the New York State Department of Health² on this subject

have recently been summarized at the request of a group of hospital administrators and health officers and are worth quoting.

In the early part of this century, there was a tendency on the part of municipalities to build special hospitals for the isolation of communicable diseases. These so called 'pest houses' were designed particularly for the care of smallpox cases but were intended for the isolation of other acute infectious diseases as well. At that time, it was thought feasible to control communicable diseases in communities through isolation of recognized cases since it was felt that if all patients were isolated until they were no longer infectious, the spread of these diseases would cease. However, upon further investigation from a bacteriological standpoint it was learned that in many communicable diseases symptomless carriers and atypical cases which ordinarily would not be recognized as infectious are frequently more important in the spread of the disease in the community than the typical cases which can be detected. The routine hospitalization of acute communicable diseases for the sole purpose of limiting spread of the infection in the community, therefore, obviously would not accomplish this objective.

At present, hospitalization of contagious diseases ordinarily is recommended only in those cases requiring care from the standpoint of the welfare of the patient himself and which can be given only in a hospital and not at home. In rare circumstances, it may still be necessary to hospitalize patients from the standpoint of the protection of the community as, for example, in the case of a communicable disease discovered in a transient or occurring in a home in which for certain reasons proper isolation is impossible.

Concomitant with the development of our bacteriological knowledge of communicable disease, techniques have been devised to permit the safe isolation of cases of communicable diseases in general hospitals. These procedures vary with the disease; some patients can be cared for without danger on a ward, others must be confined to a private room. However, there is essentially no communicable disease which cannot be cared for safely in a private room on a floor on which there are other patients with noncommunicable diseases, providing certain techniques are practiced rigidly by the attendants. It has become increasingly clear that the training and skill of the attendants are much more important in controlling the spread of infection than the physical equipment provided.

In the opinion of the New York State Department of Health, therefore, separate buildings for the sole care of communicable diseases are not essential. In larger municipalities it may be more convenient for a hospital to have a separate building for this purpose but this is a matter of convenience and not necessity. In smaller places in which such a building would be vacant a large part of the time, an unnecessary expense to the community would be entailed.

Every hospital is dealing with communicable diseases whether or not it recognizes that fact. Because of the prevalence of carriers and atypical cases among the general population, it is inevitable that such carriers and cases will be admitted from time to time to a hospital even though the infection is not detected at the time of admission. The routine procedures followed in these hospitals, therefore, with regard to the hygienic practices of the

HOSPITALIZATION FOR ACUTE COMMUNICABLE DISEASES

THERE are many good reasons for reconsidering the role of special contagious-disease hospitals. In recent years a definite change in attitude toward certain diseases has occurred, and they have been taken out of the class of those that are considered suitable for isolation in special hospitals. An example of immediate interest is meningococcal meningitis. In the past, cases of this disease have been considered especially suitable for care in isolation hospitals but now they are being treated in the wards of general hospitals without difficulty. The problem of isolation and quarantine in cases of scarlet fever has been considered in a recent edi-

torial in the *Journal*.¹ It is quite incongruous in the light of present-day understanding of streptococcal infections to consider scarlet fever as the only one of a group of hemolytic streptococcal diseases that requires isolation in special contagious-disease hospitals, while patients with tonsillitis or septic wound infections are treated in the operating wards or in single rooms of general hospitals. Smallpox may be considered as an extreme example. But even with this disease the facts that vaccination against it is practically universal and that the immunity of the hospital personnel can be maintained by frequent revaccination make it perfectly feasible to treat cases of this disease in single rooms in general hospitals.

General hospitals are, willingly or otherwise, treating cases of all sorts of communicable diseases at the present time. Many patients are admitted before the correct diagnosis is made and when they are presumably at the height of their contagiousness and when the possibility of communicable disease is entertained, the staff of the hospital must be prepared to use proper technic to avoid transfer of infection to themselves and to others. This makes quite essential for the entire staff to be acquainted with the technics that limit the spread of contagious diseases.

The diagnosis and care of open cases of tuberculosis, although different in many respects from those of other acute communicable diseases, present some problems along the same line. The special hospitals for the care of such cases are over-crowded, and even when beds in such sanatoriums are available, many patients are loath to take advantage of their facilities. General hospitals, particularly large municipal hospitals, are constantly called on to receive such patients and to keep them for long periods, pending their final placement in suitable institutions. During this time, the open cases of tuberculosis are in many ways similar in their contagiousness to other cases of the more acute infectious diseases. Arrangements for the management should be adequate to minimize the spread of disease among the hospital contacts, and such arrangements are nowise different from those necessary for the care of patients with other communicable diseases.

hours to tell me that a boy was having convulsions. He had broken his ankle three days before, and she suggested that he might have had an embolus to explain the convulsions. She said his respirations were 58 and his pulse rate 60! Leaving several patients in the office I dashed to the school at sixty miles an hour to find the boy asleep and, when waked up totally oblivious that anything was wrong with him. His pulse was 76 and his respirations were 16. I became incoherent and if I said anything it was only to mention the name of the deity over and over. After she saw that I was unsympathetic to the embolism theory, she suggested it might be epilepsy. I tore my hair again, but it did no good.

A few days later she again called me up—"urgently"—to tell me that a boy whose ankle I had strapped had suffered agonizing pain" all night, that the strapping had caused great swelling and that he had paralysis of the foot and ankle. She had me worried, because I did not believe that she knew enough to make up such a story. I had visions of meeting the boy's parents face to face and trying to explain how I had not caused the paralysis, how these things happen once in a while and how extremely unfortunate it was. I was willing to admit that perhaps I had put on the strapping a little too tightly. So in an agitated frame of mind I made my way to the school to find a foot that was normal in every respect except for the swelling caused by a badly sprained ankle.

A while ago there was a measles epidemic. Every day there were three or four new cases. Toward the end of the epidemic the nurse became tired and nervous, and her mind which normally was extremely extensible had reached the explosive stage. While walking with her across the campus she told me she had found a dead rat. I did not say a word. I knew what was working in her mind. Sure enough, the next day the wires began to burn again and after paging me over the countryside she at last got me on the telephone. There are two more down," she said, "I don't like it, I don't like it. I think you ought to come to the school immediately." I took my time in getting there, and on arrival found that another doctor had preceded me. I asked her what all the excitement was about. She wouldn't tell me but I knew she had made the diagnosis of bubonic plague!

And so I live from day to day, almost in a state of collapse with the sword of Damocles hanging by a thread above my neck.

NOTICES

POSTON SOCIETY OF BIOLOGISTS

A meeting of the Boston Society of Biologists will be held at the Surgical Amphitheater (3A) of the White Building, Massachusetts General Hospital, on Wednesday, April 19 at 8 p.m.

PROGRAM

The Physical-Chemical Properties of the Plasma Proteins and Their Concentration into Fractions of Differing Functions. Drs. E. J. Cohn, L. E. Strong, J. L. Oncley, W. L. Hughes, Jr., and S. H. Armstrong, Jr.

Fibrinogen and Thrombin and the Products Derived from Them. Drs. J. D. Ferry, J. T. Edsall, E. A. Bering Jr., and P. R. Morrison.

Immunological Studies on the Plasma Proteins. Dr. J. F. Enders.

Clinical Investigations with Albumin and Immune Globulins. Drs. C. A. Janeway, L. Woodruff and C. Ordman.

Clinical Investigations with Products of Fibrinogen and Thrombin. Drs. O. T. Bailey and F. D. Ingraham.

SOUTH END MEDICAL CLUB

The next regular meeting of the South End Medical Club will be held at the headquarters of the Boston Tuberculosis Association, 554 Columbus Avenue, Boston, on Tuesday, April 18, at 12 m. Dr. Vlado A. Getting will speak on the subject, "Tropical Diseases."

Physicians are cordially invited to attend.

MASSACHUSETTS CENTRAL HEALTH COUNCIL

Featuring a panel entitled "Should Social Security Be Extended Farther into the Fields of Medical Care and Hospital Service?" the annual meeting of the Massachusetts Central Health Council will be held at the Pioneer Y W C A, 140 Clarendon Street, Boston, promptly at twelve noon on Friday, May 5. After a buffet lunch (80 cents) and a brief business meeting the panel discussion with the president, Dr. George C. Shattuck, acting as chairman, will proceed.

G. F. Houser, M.D., first assistant director, Massachusetts General Hospital, and Walter G. Shippen, M.D., member of the Massachusetts Medical Society.

Nurses and social workers, as well as physicians, are cordially invited to attend. Luncheon reservations should be sent to the secretary, Arthur J. Strawn, 1148 Little Building, Boston 16.

NEW ENGLAND SOCIETY OF ANESTHESIOLOGY

The next meeting of the New England Society of Anesthesiology will be held in the Bigelow Amphitheater of the Massachusetts General Hospital on Tuesday, April 11, at 8 p.m. Dr. K. M. Heard will speak on the subject, "Benefits and Hazards of Pentothal."

NEW ENGLAND DERMATOLOGICAL SOCIETY

The annual meeting of the New England Dermatological Society will be held in the Skin Out Patient Department of the Boston City Hospital on Wednesday, April 12, at 2 p.m.

NEW ENGLAND OPHTHALMOLOGICAL SOCIETY

A meeting of the New England Ophthalmological Society will be held at the Massachusetts Eye and Ear Infirmary, 243 Charles Street, Boston, on Tuesday, April 18, at 8 p.m.

Following the business meeting, John Marquis Converse, a major in the Medical Corps of the French Army, will show a motion picture. Dr. Walter B. Laneaster will then speak on the subject, "Some Chestnuts from My Stock Pile."

NEW ENGLAND OTOLARYNGOLOGICAL SOCIETY

The regular spring meeting of the New England Otolaryngological Society will be held at the Massachusetts Eye and Ear Infirmary on Wednesday, May 10.

NEW ENGLAND PATHOLOGICAL SOCIETY

The annual meeting of the New England Pathological Society will be held at the Harvard Club, Boston, on Thursday, April 20. Following the dinner at 6 p.m., Dr. Tom Spies will speak on the topic, "Pathological Changes Occurring in Certain Vitamin Deficiencies in Man."

UNITED STATES CIVIL SERVICE COMMISSION

While on battlefronts scattered throughout the world our Armed Forces are concentrating on winning the war, in Army and Veterans' hospitals here in the United States trained occupational therapists are among those lending their efforts toward winning the peace.

These therapists are erasing the ravages of war by the systematic rehabilitation of injured bodies and minds. Some

of the war-wounded are reconditioned for further service in the Army; others are fitted for useful civilian work in a normal environment.

As increasing numbers of injured soldiers return to the hospitals, more and more occupational therapists are needed to aid in their adjustment to normal life. In greatest demand are experienced graduates of accredited schools of occupational therapy. Experience should be in hospitals acceptable to the American Medical Association. For some positions, however, college training in psychology and in arts and crafts or trades and industries, or experience as a junior aide in Veterans' hospitals, may be substituted for training in occupational therapy schools. Other positions will be filled by inexperienced graduates of occupational therapy schools.

The salary range of these positions is \$1970 to \$2433 a year, including overtime pay. Those appointed at \$1970 will be trainees for a period of eighteen months; those appointed at \$2190 and \$2433 will administer occupational therapy under medical and general supervision in Army and Veterans' hospitals.

There are no age limits and no written tests, but applicants must be physically capable of performing the duties involved. Persons now using their highest skills in war work should not apply. Federal appointments are made in accordance with War Manpower Commission policies and employment stabilization programs.

Further information on occupational-therapy aide positions and forms for applying can be obtained from first-class and second-class post offices or from the United States Civil Service Commission, Washington 25, D. C.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, APRIL 13

THURSDAY, APRIL 13

*9:00-10:00 a.m. Medical clinic. Dr. S. J. Thannhauser. Joseph H. Pratt Diagnostic Hospital.

FRIDAY, APRIL 14

*9:00-10:00 a.m. Treatment of Amputees in the Services and Later. Rear-Admiral R. H. Laning (MC), U.S.N.R. Joseph H. Pratt Diagnostic Hospital.

SATURDAY, APRIL 15

*10:00-11:30 a.m. Medical staff rounds. Peter Bent Brigham Hospital.

MONDAY, APRIL 17

*12:15-1:15 p.m. Clinicopathological conference. Peter Bent Brigham Hospital.

TUESDAY, APRIL 18

*9:00-10:00 a.m. Medical clinic. Dr. S. J. Thannhauser. Joseph H. Pratt Diagnostic Hospital.

*12:00 m. Tropical Diseases. Dr. Vlado A. Getting. South End Medical Club. Headquarters of the Boston Tuberculosis Association, 554 Columbus Avenue, Boston.

*12:15-1:15 p.m. Clinicoroentgenological conference. Peter Bent Brigham Hospital.

WEDNESDAY, APRIL 19

*12:00 m. Clinicopathological conference. Children's Hospital.
8:00 p.m. Boston Society of Biologists. Surgical Amphitheater (3A) of the White Building, Massachusetts General Hospital.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

American Standard Definitions of Electrical Terms. 4°, cloth, 311 pp. New York: American Institute of Electrical Engineers, 1943. \$1.00.

This authoritative reference work was compiled by a special committee representing thirty-three organizations in the electrical field and organized by the American Institute of Electrical Engineers. The committee was enlarged by the appointment of eighteen subcommittees with a total membership of one hundred and twenty, to which were added numerous nonmember experts, so that, in all, over three hundred authorities in all fields aided in the compilation. The primary aim of this glossary is to express for each term the meaning that is generally associated with it in electrical engineering in the United States. The preferred definition is a simple one, with a single statement of function rather than explicit description of all properties included and excluded. The arrangement is by special groups and subsidiary sections. The numbering used to identify terms is based on a system proposed for use by the International Electrotechnical Commission. Groups 75 and 80, having to do with radiology and electrobiology, including electrotherapeutics, are of medical interest. There is an extensive, comprehensive index. The work is well arranged and well printed on good paper in a good binding and sold at a nominal price. It should be in all medical libraries, as well as in the offices of all physicians interested in radiology and electrotherapeutics.

Lincoln-Douglas: The weather as destiny. By William F. Petersen, M.D. 8°, cloth, 211 pp., with 16 illustrations. Springfield, Illinois: Charles C Thomas, 1943. \$3.00.

The author contends that the relation between the human body and the atmosphere in which it functions is of primary importance and that this relation must be understood if man is to make any progress in adjusting himself to the inexorable conditions of existence. His thesis has been built around the famous Lincoln-Douglas controversy.

Medical Clinics on Bone Diseases: A text and atlas. By I. Snapper, M.D. 4°, cloth, 225 pp., with 30 plates and 39 tables. New York: Interscience Publishers, Incorporated, 1943. \$10.75.

In this book are presented observations and x-ray pictures especially chosen to elucidate some of the problems involved in the recent expansion of knowledge of bone diseases. The comparison of experiences is made between conditions in the Western Hemisphere and those in China.

The manner of injury to the head was in most cases remarkably similar. Eighteen patients (46 per cent) had fallen downstairs or on paved streets, type of accident especially frequent among alcoholic patients. Full details concerning such accidents were rarely obtainable, since most of these patients were found lying on the sidewalk in a comatose condition. Traffic accidents were responsible for the next largest group (36 per cent), and a majority of incidents accounted for the remainder.

DEFINITION OF TERMS

The duration of the post-traumatic psychosis is its intellectual, emotional and personality disturbances, may extend well into weeks or months and the end is often difficult to define. The period of disorientation can be more definitely delimited, and in these cases was ascertained by asking specific questions pertaining to time, place and situation, repeated at daily intervals. For the purposes of this study it was therefore found convenient to regard confusion as synonymous with disorientation in one or more spheres, and the data have been arranged according to the duration of such confusion. Coma and semicoma were considered ended when the patient was able to respond recognizably to calling name.

In Table 1 the frequency of abnormal signs is listed. In Tables 2 and 3 a number of findings are analyzed with regard to their duration. Short, medium and long periods of confusion were arbitrarily chosen so that a similar number of cases in each group would be available for comparison. A separate listing of patients who died was dictated by the fact that death rather than recovery terminated the end of the confusion, and only those patients who died after three days have been included. The temperature, pulse and respirations were considered to have returned to normal when elevations of these vital signs did not exceed the accepted norm¹⁰; in addition, the occurrence of abnormally high or low values was noted. Blalock's¹¹ definition of surgical shock was followed. Many abnormal findings were obtained on neurologic examination, but only Babinski's sign and inequalities or absence of tendon reflexes occurred with sufficient frequency to be tabulated. Focal or generalized disturbances of frequency in the electroencephalographic tracings were regarded as attributable to the head injury, in accordance with the criteria of studies reported in the literature.¹² Some of the terms used are self-explanatory, but others demand arbitrary definition. Acute alcoholism was recorded when the odor of alcohol on admission was substantiated by a history of considerable intake immediately before the accident, habitual use of alcohol to excess, with frequent arrests for drunkenness or a history of delirium

tremens, was considered evidence for alcoholism. Apathy was defined as a state in which the patient shows no interest in his own condition, his physician or his surroundings. The period during which the patient could not respond to psychologic tests was measured by ability to co-operate in such simple tasks as serial subtraction or study of absurd pictures. Data regarding the manner in which the response to such psychologic tests is disturbed following head injury have been analyzed and presented elsewhere.¹³ The ability to co-operate in any degree in such tests is here recorded as a stage in the recovery process. Drowsiness was regarded as a condition in which the patient tends to fall asleep repeatedly during the ordinary waking hours. In hospital records such variable states as semicoma, confusion, apathy and lack of speech are often described as stupor. We have used this word to describe those patients who were able to eat or drink and maintain body position but failed to give any verbal responses. The term "incoherence" is used to describe the condition, irrespective of its etiology, in which speech was disorganized, reaching the extreme in a confused mixture of words. In this study the use of the term "perseveration" has been limited to repetition in speech. An abnormal sense of well being has been described as "euphoria," and a morbid impulse to joke as "mania." Patients who had difficulty in adjusting to the hospital environment after they were sufficiently recovered to be ambulatory on the ward were considered behavior problems.

In evaluating the status during the immediate follow-up period, dementia was adjudged to be present when disorientation still existed after three months. In those patients designated as intellectually impaired, the psychometric findings were well below the range that could be expected from the school and occupational histories. Except where actual measurements such as those of pulse, temperature, respirations and spinal fluid pressure could be used, only the presence or absence of certain features was noted, since the degree was a matter of interpretation.

CLINICAL DATA

Frequency of Signs

The principal abnormal findings are presented in order of frequency in Table 1. Abnormal electroencephalographic findings (93 per cent), bloody spinal fluid (90 per cent) and elevated spinal fluid pressure (74 per cent) occurred in the great majority of cases. Babinski's sign (67 per cent) and skull fracture (65 per cent) were next in frequency. This tabulation focuses attention on the high incidence of the presumptive evidences of severe brain damage in patients with prolonged confusion as a result of head injury.

Many compound or depressed skull fractures, together with the intracranial hemorrhages, re-

We are indebted to Dr. Charles Brenner for the electroencephalographic

counted for the large number of operations in this series. The frequency of subdural or extradural hemorrhage (27 per cent) indicates that these complications should be carefully considered in con-

fused patients. During their early hospital course 15 per cent of the patients experienced convulsive seizures.

Intellectual disturbances, such as perseveration, confabulation and dysphasic disorders, outnumbered other mental abnormalities. Ten patients (26 per

It is worth noting that a great number of signs were comparatively infrequent in the patients in whom the duration of confusion was short (Table 2). Patients disoriented for less than twenty days did not have convulsions or incoherence, although the incidence (40 to 60 per cent) was fairly high in those confused for twenty-one days or over. Likewise, neither stupor nor a temperature above 103°F. was found in patients disoriented for less than ten days. In contrast to these findings, there were signs that were no less frequent in the patients in whom confusion was of short duration. Among these were abnormal electroencephalograms, Babinski's sign, significant respiratory, pulse and blood-pressure changes, complicating extracranial injuries and surgical shock. Apathy, euphoria and moria were actually more frequent in the patients who were disoriented for less than ten days than in others.

Acute and chronic alcoholism occurred in well over half the cases. The mean duration of confusion in the alcoholic group (nineteen days) was considerably longer than that in the nonalcoholic group (eleven days). It should be pointed out, however, that the mean age of the alcoholic patients was also greater than that of the other subjects (forty-six as compared with thirty-one years).

Not mentioned in the tables were the following features that occurred in relatively few cases. Eight patients (21 per cent) had a history of previous head injury. Three showed a lucid interval between an initial and later period of confusion, and 2 exhibited marked fluctuation in the level of consciousness. Four of these 5 patients were found to have sub-

cent) presented behavior problems on the ward. Apathy and marked irritability were encountered in about a third of the cases. Hallucinations were relatively rare (14 per cent), and with the exception of 1 case occurred only in acute or chronic alcoholic patients.

dural hematomas, and in the fifth the right frontal lobe had been traumatically amputated. The 3 patients with dementia exhibited an abnormally increased appetite.

The 5 patients who died during their initial hospitalization represented particularly severe head

uries with complications. Four had sustained all fractures — 3 basilar and 1 compound. All had perience contusion and laceration of the brain.

The 4 with subdural hemorrhages, 3 died within the first six days, 2 of them despite operation; the fourth lingered for twenty days, finally dying of septicemia. A seventy-two-year-old man lived for twenty-three days and developed an acute terminal meningitis with epileptiform seizures. At autopsy it was found to have an old *plaque jaune* with a large area of recent softening, in addition to some contusion and laceration. One patient was explored a second time for a subdural hematoma when he failed to improve after removal of a large subdural hemorrhage, but only an extensive area of softening was discovered. An elderly woman with a compound skull fracture, multiple fractures, early surgical shock and subdural hemorrhage remained in coma for six days before death.

Duration of Signs

The mean duration of the various findings is shown in Figure 1. The ability to speak returned early, on an average during the first day, and usually immediately after the reappearance of reflex activity as coma subsided. The first response to simple psychologic tests was not attained until the second week, but this degree of improvement was preceded by correct orientation in place, situation and time. Of the vital signs, the respirations returned to normal first, then the temperature and last the pulse. As might be expected, the duration of abnormal signs varied directly according to the duration of confusion, although pulse fluctuation was an exception to this general rule.

In Table 3 it will be seen that the order of events in recovery varied in the three groups of confused

to those with less prolonged confusion. Restlessness requiring restraint lasted relatively longer in the patients with moderate durations of confusion than in those with shorter or longer disorientation.

None of the patients who died responded to the simplest psychologic tests before death, and 80 per

FIGURE 1. Duration of Abnormal Signs in 30 Cases with Prolonged Confusion following Head Injury.

cent of those longest confused were not testable during hospitalization. Only 13 per cent of those disoriented for ten to twenty days were completely incapacitated in this respect throughout their stay, whereas subjects with the shortest confusion could

*In the patients who died many signs persisted until death, and the duration of the sign in each case was the same as for the period from injury to death. The mean duration was calculated, nevertheless, in order to show that some signs persisted longer on the average than did others, even when death supervened.

patients who ultimately recovered. The variations chiefly concern the duration of abnormalities in respiration, temperature and pulse. The order of recovery from speechlessness, incontinence and disorientation in place, situation and time was the same in all. Drowsiness persisted longer in relation

to those with less prolonged confusion. Restlessness requiring restraint lasted relatively longer in the patients with moderate durations of confusion than in those with shorter or longer disorientation. If these values are converted into figures applicable to all cases of head injury

studied at this hospital, regardless of duration of confusion, approximately 2 per cent of all patients had marked and probably permanent intellectual defect at the end of three months.

All 14 cases listed under the heading of dysphasia suffered from impairments in perception and execution associated with confusion. Understanding of

light of the long disturbances of consciousness in these patients, however, some consideration is due to their course during the first six months after discharge from the hospital (Table 5). Five patients died during their initial hospitalization after a period of confusion varying from four to twenty-three days; a sixth, who remained demented for

spoken and written language, as well as ability to read and write, was disturbed in all cases. In only 4 patients was the disturbance of speech such as to indicate localized cerebral damage, and of these, two had a "jargon dysphasia." The majority of

more than three months after removal of a subdural hematoma, died after a second exploratory craniotomy. Four patients could not be adequately followed. In 2 cases satisfactory reports concerning the patients were received from other institutions. The remaining 27 patients were examined one or more times in the Head-Injury Clinic of the Boston City Hospital and were followed for at least six months after injury.

A relatively large percentage (38 per cent) of patients remained asymptomatic during the six-month follow-up period. In general, symptoms did not begin after discharge but were existent throughout the post-traumatic course. Sixty-two per cent of patients who were followed had some complaint attributable to their head injury, but in only 2 cases were the symptoms severe. Nine patients had two or more of the symptoms listed in Table 5, whereas 4 presented the classic triad of headache, dizziness and easy fatigability. Headache and dizziness, whenever present, usually lasted for at least two to four months, and in 5 cases each was present for longer than six months. Residual neurologic signs were found in 9 cases (31 per cent), and in most of them persisted in some degree for the entire follow-up period; 2 patients developed epileptiform seizures late in their course. Those patients with marked intellectual impairment a few weeks after injury continued to show the same defect in diminishing degree for at least six months; the incidence of intellectual defect at the end of three and of six months was approximately the same. All 4 cases with dysphasia improved considerably, and at the end of six months it was difficult to demonstrate any defect in 3. Two thirds of the patients who were followed had returned to their usual occupations within six months after injury, and only 14 per cent could be considered completely incapacitated by their head injury at the end of this time.

*All patients were followed for at least six months, but the figures do not always represent the findings at the end of that time. The signs and symptoms listed were present for variable periods of time following hospitalization.

†There was, of course, some overlapping, some patients having more than one symptom or sign.

‡Patients with dementia are not listed with those having marked personality change, but 5 patients with partial intellectual impairment were adjudged to have striking personality disorders as well. We are indebted to the other members of the research group for data on the ultimate follow-up, and particularly to Dr Edwin M. Cole for a report on the intellectual status of the patients.

these patients had a disturbance in the understanding of the meaning of sentences that lasted longer than the period of disorientation.

Comparison of the durations of coma or semicoma and mental confusion (Table 4) shows that the relation between the two was not direct.

COURSE AFTER HOSPITALIZATION

Discussion of the late effects of severe injuries to the head is beyond the scope of this paper. In the

DISCUSSION

Prolonged confusion resulting from head injury was accompanied by important changes in vital

is in about half the 39 patients, and the duration of such changes did not seem to be significantly related to the duration of confusion. From these observations, it seems safe to conclude that mental confusion in patients with head injuries is not merely the result of respiratory or peripheral circulatory disturbances or elevated body temperature. The evidence, on the other hand, indicates that prolonged confusion is the direct result of severe trauma to the brain, a conclusion supported by the high incidence of findings indicating cerebral damage, such as an abnormal electroencephalogram, bloody spinal fluid under increased pressure, extensor plantar responses and skull fracture. From the data obtained in this small series it is not justifiable to conclude that confusion results from increased pressure, the presence of blood in the spinal fluid or a combination of these. Indeed, we are well aware of many cases in which all these are present without prolonged confusion. No combination of signs, apart from those of the mental disorder consequent on the confused state, was invariably present. From the prognostic standpoint, the presence of convulsions during the hospital course, incoherence, stupor or a temperature over 101°F. was particularly important in this series, and these signs were found only in association with the longest confusion. This evidence also supports the theory that fever in such injuries is of cerebral origin, as indicated by Goldstein.¹⁴ The duration of the period of disorientation was prolonged by advancing age and by alcoholism.

Among 190 unselected patients with head injuries previously reported,⁹ 9 per cent were in a state of coma or confusion during the first twenty-four hours. The series studied here, in which coma or confusion persisted for longer than three days, constitutes 8 per cent of a larger but overlapping group. These figures suggest that when confusion is present for more than twenty-four hours, it is usually associated with severe cerebral damage and is apt to persist for days or weeks. Although short-lasting disorientation is usually encountered immediately after head injury, this type of disturbance tends to be limited to minutes or hours, and is probably related to alcoholism, to a memory gap or to the emotional factors attendant on loss of consciousness. In this small series it is interesting that euphoria, apathy and apathy were more frequent in the patients in whom the period of confusion was short. It is possible that severe intellectual impairment precedes these emotional and personality disturbances, which become more evident when orientation returns.

The order in which the various abnormalities appeared is constant for speechlessness, incoherence and disorientation in place, situation and person. These are milestones in a gradually progressive improvement in cerebral function. There is,

however, a diurnal fluctuation most noticeable in any function for the first few days after its reappearance. In relation to these events in mental awakening, drowsiness and restlessness hold no fixed place, disappearing relatively earlier in the more lengthy confusions. It is possible that they reflect disorder of a different kind,—for example, emotional reaction—for the person with limited consciousness is still capable of such reaction. The duration of abnormality of pulse rate may likewise be related to emotional disturbance as well as to damage to vital centers. Its inconsistency reveals such multiple relations. The motor manifestations, such as inability to speak and extreme restlessness requiring restraint, disappear long before the intellect returns to normal. The duration of the period in which the patient is unable to make any response to simple psychological tests was found to be a measure of the severity of the confusion, for the duration of such disability was related to the duration of the period of confusion. The first responses were made shortly before normal orientation reappeared.

The cases here reported are included in a larger group investigated by us,⁹ in which the incidence of severe intellectual impairment at the end of three months was about 2 per cent. All the patients in the present series with persisting intellectual defect at the end of three and six months had a period of disorientation in excess of nineteen days, an indication that both these disturbances are aspects of the same essential disorder of cerebral function. The mental phenomena of the confused state can be regarded as the initial deeper stage of what later becomes intellectual impairment. This disturbance is complicated by the influence of age and alcoholism. No cases were encountered of disproportion between the severity of confusion and the degree of residual mental defect of the type mentioned by Symonds.⁶ These patients are being followed for long periods by the other investigators in the project, and our present intention is simply to give an indication of the clear relation between the early confusion and the later disturbances of the intellectual sphere.

The duration of amnesia is closely related to that of confusion. All the patients in this series appeared to have retrograde and post-traumatic amnesia, but reliable estimate of its duration was obtainable only in retrospect after disorientation and other disturbances had entirely cleared. In the early stages of hospitalization, therefore, the duration of confusion (disorientation) is the best criterion for evaluation of the severity of damage to mental function. Unfortunately, such information is often unavailable when patients are seen late in convalescence, and the post-traumatic period of amnesia is then the only basis on which the duration of disturbed consciousness can be estimated. Whereas post-traumatic amnesia appears to coincide, fairly well in duration

with disorientation, measurement of the latter would provide more reliable and more easily obtainable objective data.

SUMMARY

In 39 patients with prolonged disturbances of consciousness following head injury, the frequency and duration of abnormal signs were analyzed. A high incidence of abnormal findings, such as an altered electroencephalogram, skull fracture, bloody spinal fluid under increased pressure and Babinski's sign, gave evidence that prolonged mental confusion is associated with severe brain damage. Important changes in vital signs were present in only half the cases and appeared to be independent of the presence and duration of confusion.

During the period of hospitalization immediately following injury, intellectual disturbances outnumbered other mental abnormalities. Emotional disorders tended to appear later than the cognitive dysfunctions, and persisted longer; they were frequent even in cases of short confusion.

Ability to speak returned on an average within the first day. The first response to simple psychologic tests appeared during the second week, before correct orientation in place, situation and time, which returned in that order. Drowsiness and restlessness held no fixed place in the order of recovery, and appear to be independent of the course of recovery of intellectual function.

Gross intellectual defect persisted for six months in 31 per cent of the series, and in every case was preceded by a period of confusion lasting longer than nineteen days.

The duration of disorientation proved to be one of the most reliable and easily obtainable criteria of the seriousness of mental prognosis. The duration of post-traumatic amnesia is directly related to the period of disorientation and thus of equal value, but is available only later and is thus a purely subjective quantity.

MENINGOCOCCAL MENINGITIS*

A Report of Thirty-Three Cases with No Deaths

LIEUTENANT RALPH R. MEYER, M.C., A.U.S.

CAMP GRANT, ILLINOIS

THIRTY-THREE cases of meningococcal meningitis were admitted to the Contagious Disease Service of the Station Hospital at Camp Grant, Illinois, between January 4 and July 3, 1943. During this period, there were 10 additional cases of acute purulent meningitis, with 1 death. No organisms were found either on repeated spinal-fluid examination or on blood culture. Because the etiology of these cases is not clear, they are not included in this discussion.

Four cases are presented in detail, including one that was complicated by hemorrhage into the adrenal glands (Waterhouse-Friderichsen syndrome). All the patients were adults between the ages of eighteen and thirty-four years.

frequently there was an associated cough, sore throat and nasal discharge. The admission temperatures varied from 98 to 104.4°F., with an average

TABLE 1. Frequency of Symptoms.

Cough	11	33
General aching	8	24
Nasal discharge	6	18

of 100.8°F. Fever persisted on an average of five days, with a variation of one to fifteen days.

Physical Signs

A rigid neck was present in all 33 patients, and a positive Kernig sign was elicited in all but one (Table 2). Coma, semicoma or drowsiness occurred frequently. Skin manifestations, usually in the form of petechiae, were not uncommon. Occasional

Symptoms

In most cases the onset was acute, with severe headache, chills, fever and vomiting (Table 1). Less

*From the Medical Service, Station Hospital, Camp Grant, Illinois.

a generalized pink macular or maculopapular rash was seen. Neck rigidity persisted on an average of 6.6 days, with a variation of two to seventeen days.

Laboratory Findings

A total and a differential cell count, a Pandy's test, a sugar determination, a stained smear and a culture on chocolate agar (incubated in an atmos-

phere containing 10 per cent carbon dioxide) were routinely performed on all spinal fluids. In all but 1 case, the diagnosis of meningococcal meningitis was confirmed by the presence of the characteristic gram-negative intracellular diplococci in the smear of the spinal fluid or by their isolation in culture. In the remaining case, which presented the typical clinical and laboratory findings of an acute meningitis, the organisms could be isolated only in blood culture. On initial examination the spinal fluid was frankly purulent in all but 2 patients. The first lumbar puncture in these cases revealed a clear, colorless fluid containing only a few lymphocytes, but a tap repeated several hours later revealed the presence of many polymorphonuclear leukocytes.

Eighteen of the 33 patients had spinal-fluid cell counts of 5000 to 20,000, with 74 to 100 per cent polymorphonuclear leukocytes (Table 3). The

organism was seen in the spinal-fluid smear in 27 cases (82 per cent). Spinal-fluid culture was positive in 26 cases (80 per cent). Group I meningococci were found in all cultures that could be successfully typed (21 cases). In only 17 cases (51 per cent) was the spinal-fluid sugar decreased. Eleven patients (33 per cent) had a positive blood culture. The white-cell count of the blood in most cases varied between 15,000 and 25,000, with a moderate to marked polymorphonuclear leukocytosis.

Treatment

Treatment in almost all cases was begun in twenty-four hours or less after the onset of symptoms. Sulfadiazine, sulfathiazole and polyvalent antimeningococcus serum were used singly or in

combination. The way in which these therapeutic agents were employed is summarized in Table 4.

When sulfathiazole and sulfadiazine were used in combination, intravenous sodium sulfathiazole was the drug employed to initiate treatment. This was followed by oral sulfadiazine as soon as the patient was able to take medication by mouth. When sulfadiazine was used exclusively, the sodium salt of sulfadiazine was substituted for the sodium sulfathiazole, which was used only when sodium sulfadiazine was not available, the latter drug being preferred because of its lower toxicity. In general, treatment was initiated by giving intravenously 5 gm. of sodium sulfadiazine or sodium sulfathiazole dissolved in 100 cc. of distilled water. If oral sulfadiazine could not be given within twelve hours after the onset of treatment, the intravenous administration of sulfonamide was repeated. As a rule it was unnecessary to repeat the parenteral injection more than once, since at the expiration of twenty-four hours the patient was usually able

TABLE 4. Type of Treatment.

THERAPEUTIC AGENT OR AGENTS	NO OF CASES	PERCENTAGE

Sulfadiazine and serum	2	6
Sulfadiazine, sulfathiazole and serum ..	3	9

to take sulfadiazine by mouth. When oral therapy was begun, 1 or 2 gm. of sulfadiazine was given every four hours, the larger dose usually being employed for only twenty-four to forty-eight hours, depending on the blood level of the drug. Thereafter, sulfadiazine was continued in doses of 1 gm. every four hours until the patient was afebrile for one week, whereupon therapy was abruptly discontinued. Since most patients were afebrile after the fifth day, the average case received sulfadiazine for eleven or twelve days.

The dosage of sulfadiazine was governed to some extent by the blood level of the drug. An attempt was made to obtain a blood-sulfadiazine level of 8 to 12 mg. of the free drug per 100 cc., preferably by the second day of treatment. When the blood level was much below 8 mg., however, no attempt was made to increase the blood level by giving larger than the usually recommended doses of sulfadiazine if the patient seemed to be making satisfactory progress. In Table 5 are given the blood and spinal-fluid sulfadiazine levels of 14 patients who received sulfadiazine exclusively.

The twenty-four-hour fluid intake and urinary output were measured for all patients receiving sulfonamide therapy. This was considered to be of the utmost importance. A urinary output of not less than 1500 cc. every twenty-four hours was desired. If it was less than this, fluids were forced by mouth or intravenously to prevent anuria.

Polyvalent antimeningococcus serum was used in conjunction with a sulfonamide drug in 5 cases.

Its use was reserved for markedly fulminating cases and for those that seemed to be responding poorly to sulfonamide therapy. Despite negative intradermal and intraocular tests in all cases, a reaction to the serum was encountered in 2 patients, chills and headache occurring during administration — apparently an anaphylactic reaction. In the remaining 3 cases, serum therapy was followed one week later by urticaria and arthralgia.

Routine spinal-fluid drainage was not performed. All patients received a minimum of two lumbar

Complications

A serious complication was encountered in only 1 case, this consisting of a probable hemorrhage into the adrenal glands (Waterhouse-Friderichsen syndrome¹⁻³). This case is presented in detail below. Another patient, who had apparently made a satisfactory recovery, returned two months after discharge with the signs and symptoms of a chronic meningoencephalitis of unknown etiology. A third patient, who had made an uneventful recovery, was discovered to have an unrelated active, minima

punctures — one for diagnosis and the other for checkup before discharge from the hospital. Indications for additional lumbar punctures were persistent, severe headache, frequent vomiting and a slow or doubtful clinical response to therapy. In the last instance, repeated spinal-fluid examination was required so that the progress of the patient could be followed more closely.

Morphine sulfate in doses of $\frac{1}{6}$ or $\frac{1}{4}$ gr. was found to be the drug of choice for the control of headache and restlessness. In delirium, however, this drug was found to be of little or no value. In a wildly excited patient with true delirium, intravenous Pentothal Sodium was used, with gratifying success. Pentothal Sodium employed in this manner has the disadvantage of an extremely short-lived effect. This difficulty was overcome by slow, continuous administration, made possible by diluting the drug with a large quantity of normal saline solution. A total of 1 gm. of Pentothal Sodium was employed. To quiet the patient approximately one fourth of this amount, or 0.25 gm., was given intravenously as a 2.5 per cent solution in distilled water. The remainder, or 0.75 gm., was added to 1000 cc. of normal saline solution and given intravenously at a rate that just kept the patient from restlessness. The administration of this solution required about six hours. Repetition of the drug was unnecessary. The usual precautions for its administration were observed, and a trained attendant was constantly present.

case of pulmonary tuberculosis. The remaining complications were minor and transient. Eleven patients (33 per cent) developed herpes simplex and 2 (6 per cent) had a transient diplopia.

CASE REPORTS

The first two cases present the usual picture of an uncomplicated acute meningococcal meningitis.

CASE 1. G. H., a 19-year-old soldier, was admitted to the hospital complaining of headache, vomiting and chills that had begun a few hours previously. The past medical history and the family history were noncontributory.

Physical examination revealed a well-developed, well-nourished, conscious but stuporous man. The temperature was 104°F., the pulse 120, and the respirations 20. Neck rigidity was marked. Kernig's sign was positive, and the deep tendon reflexes were normally active. The skin was clear. A lumbar puncture revealed a cloudy spinal fluid containing 8530 white cells per cubic millimeter, of which 90 per cent were polymorphonuclear leukocytes and 4 per cent lymphocytes. The spinal-fluid smear showed an occasional pair of gram-negative extracellular diplococci. Spinal-fluid culture was positive for Group 1 meningococci. A blood culture was negative. The blood white-cell count was 20,100 with 95 per cent polymorphonuclear leukocytes and 5 per cent lymphocytes.

The patient was given 5 gm. of sodium sulfadiazine in 100 cc. of distilled water intravenously and 4 gm. of sulfadiazine by mouth, and 1 gm. of sulfadiazine thereafter every 4 hours for 11 days.

Recovery was uneventful, all clinical signs of meningitis disappearing by the 5th hospital day. The only complication was the development on the 11th day of a drug rash and fever, which quickly subsided when the sulfadiazine was discontinued.

CASE 2. G. M., a 29-year-old soldier, had been well until 1 day prior to admission, when he developed severe headache,

ness of the neck, chills and vomiting. The past medical history and the family history were negative.

Physical examination revealed a conscious but drowsy man whose temperature was 104.2°F, the pulse 112, and the respirations 24. The skin was clear. The pharynx was slightly injected. Neck rigidity was marked. Kernig's and Brudzinski's signs were markedly positive. A lumbar puncture revealed a cloudy spinal fluid containing 22,470 white cells per cubic millimeter, of which 94 per cent were polymorphonuclear leukocytes. The globulin was markedly increased. The spinal fluid sugar level was 4.2 mg per 100 cc. Smear showed gram negative intracellular diplococci and culture of this fluid yielded Group I meningococci. A blood culture was negative. The blood white cell count was 14,400 with 74 per cent polymorphonuclear leukocytes and 20 per cent lymphocytes.

The patient was given 5 gm of sodium sulfathiazole in 30 cc of distilled water intravenously and 2 gm of sulfadiazine by mouth followed by 1 gm every 4 hours. On the 10th day, because of apparent failure to improve clinically and low blood sulfonamide level — 2.12 mg per 100 cc — 1 gm of sulfadiazine was given by mouth, followed by 2 gm every 4 hours for the next 7 days. By the 8th day of treatment the blood sulfadiazine level had reached 10.3 mg per 100 cc. Thereafter the patient received 1 gm of oral sulfadiazine every 4 hours until the 11th day, when therapy was discontinued. The only reaction possibly attributable to sulfadiazine was a transient microscopic hematuria. Recovery was uneventful. All clinical signs of meningitis had disappeared by the 7th hospital day.

The next case was probably complicated by hemorrhage into the adrenal glands.

Case 3. J. B., a 23-year-old soldier, was admitted to the hospital with a chief complaint of headache. He had been ill until 2 days prior to admission, when he developed a sore throat and a slight cough. A few hours before admission he began having severe headache, chills, fever and vomiting. Physical examination revealed an acutely ill man who was conscious but drowsy. The temperature was 103.2°F, the pulse 136, and the respirations 26. There were numerous petechiae and many areas of marked purpura over the trunk and extremities. There were also a few purpuric spots over the soft palate and a small hemorrhage beneath the left alar conjunctiva. The pharynx was moderately inflamed. Neck rigidity was marked. The Kernig and Brudzinski signs were positive. The deep tendon reflexes were normally active. The heart sounds were of fair quality. The blood pressure was 70/45. A lumbar puncture revealed cloudy spinal fluid under slightly increased pressure. The white cell count was 775 with 77 per cent polymorphonuclear leukocytes and 22 per cent lymphocytes. The globulin was markedly increased and the sugar level was 55.5 mg per 100 cc. A smear showed numerous gram negative intracellular diplococci. Cultures of the fluid and the blood were both positive for Group I meningococci. The blood white cell count was 11,000 with 95 per cent polymorphonuclear leukocytes and 5 per cent lymphocytes.

The patient was given 5 gm of sodium sulfadiazine intravenously, followed by 1 gm of oral sulfadiazine every 4 hours. A few hours after treatment was begun, he lapsed into a coma. There was slight cyanosis, the pulse became unobtainable, and the blood pressure could not be obtained. Unlike the usual picture of shock, the veins were full and the extremities were warm and moist. The blood chloride level was 216 mg per 100 cc, and the blood sugar level 97 mg. Because of the clinical picture resembling shock, the blood chloride level and the striking purpura it was thought that a hemorrhage into the adrenal glands had occurred. Accordingly the patient was given large quantities of normal saline solution intravenously, adrenocortical extract intravenously and intramuscularly, a 500-cc blood transfusion and oxygen intranasally. Within 3 hours the blood pressure had risen to 70/55. Several hours later the

patient regained consciousness. The blood chloride level several days after this acute episode was 472 mg per 100 cc.

Further treatment with sulfadiazine and intravenous polyvalent antimeningococcus serum brought about a slow but uneventful recovery.

The last case, one of unusual interest, is presented to show that meningococcal meningitis cannot be ruled out on the basis of a single negative spinal-fluid examination. It further serves to illustrate how quickly the spinal fluid picture can change.

Case 4. E. A., a 28-year-old soldier, was admitted to the hospital complaining of headache, chills, general aching, sore throat and vomiting that had begun several hours before.

Physical examination presented an acutely ill patient who was conscious but drowsy. The temperature was 100.8°F, the pulse 100 and the respirations 20. There were a few widely scattered petechiae over the trunk and extremities. The pharynx was moderately injected, the neck was slightly rigid and Kernig's sign was positive. The deep tendon reflexes were sluggish. A lumbar puncture revealed clear colorless spinal fluid under normal pressure. It contained only 6 cells per cubic millimeter, all of which were lymphocytes. No organisms were seen on smear; the globulin was not increased, and the sugar level was 83 mg per 100 cc. The blood white cell count was 46,650 with 91 per cent polymorphonuclear leukocytes.

The patient was treated symptomatically. Within a few hours the number of petechiae had increased, the neck became more rigid and Kernig's sign was more markedly positive. Five hours after the first spinal fluid examination a lumbar puncture was repeated. At that time the spinal fluid was cloudy and under increased pressure and showed a cell count of 7450 with 92 per cent polymorphonuclear leukocytes and 5 per cent lymphocytes. The globulin was markedly increased, the sugar level was 46.5 mg per 100 cc and a smear showed numerous gram negative intracellular diplococci. Culture of the spinal fluids from the two lumbar punctures showed Group I meningococci. The blood culture was also positive for meningococci.

Following treatment with intravenous sodium sulfathiazole and oral sulfadiazine the patient made an uneventful recovery.

SUMMARY

The symptoms, physical signs, laboratory findings and treatment of 33 cases of meningococcal meningitis are presented.

The therapeutic agents employed were sulfadiazine, sulfathiazole and polyvalent antimeningococcal serum.

In this unselected series of cases there were no deaths.

Only one serious complication was encountered — an apparent hemorrhage into the adrenal glands (Waterhouse-Friderichsen syndrome).

MEDICAL PROGRESS

INHALATION THERAPY*

MAURICE S. SEGAL, M.D.†

BOSTON

INHALATION therapy may be defined as the administration of gases through the respiratory system for the treatment of various types of anoxia or of oxygen want of the tissues. The indications and value of oxygen therapy have been reported by Boothby and his associates, Barach and his associates and others. The principal use of oxygen is to relieve the anoxia that occurs in a wide variety of disturbances of the circulatory, respiratory and central nervous systems, in preoperative and post-operative conditions and in military medicine. Such therapy has had an amazing growth.

Other therapeutic gases, agents and methods of maintaining respiratory function have been developed. Inhalations of carbon dioxide, helium-and-oxygen mixtures, of water-vapor and of nebulized sprays of various therapeutic agents, repeated bronchial relaxation therapy, the addition of positive pressure with oxygen or helium-and-oxygen mixtures and continuous pulmonary-arrest therapy have been increasingly employed, with successful results. It is beyond the scope of this report to review the many papers that have been written on these subjects. Only those that appear to be especially significant will be considered.

EQUIPMENT

Excellent reviews of the various types of equipment may be found in papers by Boothby and his associates,¹⁻⁵ Eckman and Barach⁶⁻¹⁰ and Ellis¹¹ and in a small manual recently published by Andrews.¹² The more frequently used methods for administering oxygen are the nasal or nasopharyngeal catheter, face masks and tents and the various types of enclosing tents. Each method has its special advantages and disadvantages. With the above methods, oxygen can be given in 40 to 70 per cent concentrations.

The development of the B.L.B. apparatus in 1938 and its later modifications^{13, 14} make it possible to administer concentrations of oxygen close to 100 per cent. This is partially a rebreathing type of apparatus and can be used for helium-and-oxygen and carbon dioxide therapy. Barach and Eckman^{6, 7} in a careful analysis reported the disadvantages of the B.L.B. apparatus — namely, the accumulation of carbon dioxide and the development of negative

and positive pressures within the mask at low flow of oxygen owing to the resistance of the sponge rubber valves. These disadvantages can be largely corrected by using high flows of oxygen. A critical discussion and analysis of the B.L.B. apparatus with determinations of the percentages of alveolar air and carbon dioxide at various flows of oxygen and comparison with the Christie and Haldan masks, appeared in the English literature in a paper by Card et al.¹⁵

In a recent paper Barach and Molomut¹⁶ describe a new modification of the Barach-Eckman apparatus. This mask is a distinct credit to the ingenuity of the authors and is of tremendous practical value. An air injector is utilized to provide accurately controlled percentages of oxygen in the inspired air. By means of an expiratory valve on the face mask, which is a comfortable one, and an inspiratory valve at the entrance to the collecting bag, rebreathing is eliminated. Accumulation of carbon dioxide and mechanical resistance to respiration are greatly reduced with this arrangement of valves. A soft latex-rubber collecting bag of 1000-cc capacity makes it possible for the patient to breathe deeply with comfort. In addition the face mask has an attached expiratory outlet that has been metered for positive pressure in expiration up to 4 cm. of water pressure. A higher positive pressure develops during dyspnea when the 4-cm. orifice is used. The apparatus can be used to deliver 40 to 95 per cent oxygen or helium-and-oxygen mixtures, with or without positive pressure. If carbon dioxide therapy is prescribed, the inspiratory valve may be removed to allow rebreathing. I^{17, 18} have used this apparatus in various types of cardiorespiratory disease and find it practical and economical. Cowart and Mitchell¹⁹ made a critical analysis of the mask and attest to its improved functional value. Epstein²⁰ compared the pressure changes taking place in the nasal piece of this apparatus with those in the nasal piece of a standard B.L.B. mask. He confirmed the previous observations by Barach and Eckman that the pressure changes during inspiration and expiration are considerably smaller with the injector apparatus than with the B.L.B. mask. When using higher concentrations of oxygen with the B.L.B. mask he observed an increasing rise of pressure against expiration. The variations in pressure in the meter mask were found to be the same at all flows and less in all cases than in the B.L.B. mask.

†Assistant professor of medicine, Tufts College Medical School; outpatient physician, Boston City Hospital; junior visiting physician, Beth Israel Hospital.

The helium-and-oxygen hood rebreathing apparatus^{9,10} is the most effective one for giving oxygen or helium-and-oxygen mixtures, with or without positive pressures. The percentage concentrations of the mixtures can be exactly controlled. Positive pressures up to 6 cm. of water can be applied to the inner surface of the lung during both inspiration and expiration. The apparatus consists of a gas-tight rotor blower, two canisters for the carbon dioxide absorber, a rheostat to determine the volume of air flow and its temperature, tubal connections, an ice-containing cabinet and a plastic hood in which the patient's head lies, with closure effected by a soft-rubber collar. In this rebreathing circuit only the oxygen is used up when enclosed. Cooling, dehumidification and removal of carbon dioxide can be efficiently carried out. The apparatus is widely employed in the treatment of severe bronchial asthma, various types of pulmonary edema and obstructive dyspnea.

A new apparatus for administering oxygen is described by Bortin.²¹ The exhaled air passes through a carbon dioxide absorber and thence into a reservoir bag. When the bag is sufficiently inflated, the purified air returns to the patient. The automaticity depends on an ingenious series of valves. This is an economical method of giving oxygen, since little, if any, of the gas is wasted. It appears to have a real value in aviation, where conservation of weight and space is important. Alveolar concentrations of oxygen and carbon dioxide at varying rates of flow have not yet been reported with this apparatus. The many mechanical factors necessary for maintenance, however, probably preclude its general use.

A new apparatus for the administration of helium-and-oxygen mixtures is described by Brubach, Crisp and Neal.²² Separate tanks of helium and oxygen are used, and safety devices regulate the flow of the two gases in accordance with the patient's needs. A safety valve prevents the flow of helium until the oxygen is turned on. An adjustable weight arrangement makes possible the maintenance of a positive pressure in the facepiece. This apparatus permits a wide selection of the percentages of the gases, and when set for 20 per cent oxygen the latter cannot fall more than a fraction of 1 per cent. It is a seemingly foolproof device if all goes well and attention is paid to the many functioning parts: valves, bellows, gauges, weights, flow meter and so forth. Any desirable combination of helium and oxygen, with or without positive pressure, however, can be given with safety and relative inexpensiveness with the most ideal apparatus — the Barach-Eckman-Molomut mask apparatus,¹⁰ previously described.

An equalizing pressure chamber for immobilizing the lungs by air pressure is described by Barach.²³⁻²⁵ The total pressures on both sides of the diaphragm are made equal. Under these circumstances adequate ventilation of the lungs is accomplished with-

out voluntary breathing and without discernible movement of the ribs and diaphragm. Four out of five patients with advanced pulmonary tuberculosis considered unsuitable for any type of collapse therapy showed a consistent response to equalizing-pressure therapy — namely, a marked gain in weight, a decrease in cough and sputum, a fall in the sedimentation rate and the temperature to normal, definite clearing of shadows on the x-ray film, including cavities, and subjective improvement. This form of therapy, although at present impractical on a large scale, shows promise for the candidate for pneumothorax or thoracoplasty with advanced pulmonary tuberculosis.

CARBON DIOXIDE THERAPY

The principal use of carbon dioxide therapy is to stimulate the respiratory center. An increase in the respiratory rate and in the depth of respirations characterizes effective therapy of this type. Carbon dioxide probably acts by increasing the acidity of the respiratory center. Increase in the acidity of the blood flowing through the carotid body and low oxygen pressures in the carotid body also stimulate breathing. In addition, carbon dioxide shifts the oxygen-dissociation curve to the right and dilates the cerebral vessels.

Physiologic Effects

In seeking to understand the rationale of carbon dioxide administration, it is well to recall that Gibbs, Gibbs and Lennox²⁷ demonstrated a selective increase in cerebral flow by an increased carbon dioxide tension. Behnke, Forbes and Motley²⁸ similarly observed an increase of 33 per cent in the diameter of the pial vessels of the cat as a result of increasing the pulmonary, carbon dioxide tension. Shaw, Behnke and Messer²⁹ also believe that, apart from the shift of the oxygen-dissociation curve to the right with high carbon dioxide tensions, increased cerebral circulation accompanying carbon dioxide inhalations in part explains the increased effectiveness of a given pulmonary oxygen tension. The supply of blood to the vital centers is augmented by the cerebral vasodilatation. The above observations offer a partial explanation of the ability of increased pulmonary carbon dioxide tension to improve the effectiveness of oxygen on the central nervous system.

Gellhorn³⁰ demonstrated that the anoxia and circulatory collapse observed in human subjects when breathing atmospheres of only 8.5 per cent oxygen could be prevented by adding 3 per cent carbon dioxide to the atmospheres breathed. He attributed this to the action of carbon dioxide in increasing the respiratory volume, venous return and cerebral blood flow, stimulating the respiratory center and shifting the oxygen-dissociation curve so that the supply of oxygen to the tissues is augmented. The anesthetist thus has a simple physi-

ologic method for increasing cerebral blood flow with mixtures of carbon dioxide and oxygen, although this is not necessary if the oxygen concentration of the anesthetic mixture is kept above 20 per cent.

It is important to know when carbon dioxide ceases to stimulate and acts as a narcotic. Brown³¹ demonstrated that the therapeutic effect depends on whether the action is stimulating or narcotic. He showed that the respiratory minute volume in healthy men was increased 279 per cent by a 10.4 per cent concentration of carbon dioxide in the inspired air, although at concentrations above 7.5 per cent the increase was negligible. Above 10.4 per cent, a decrease in minute volume from the maximum began.

The efficacy of carbon dioxide in carbon monoxide poisoning is due not merely to stimulation of respiration but, as Stadie and Martin³² point out, to the displacement of carbon monoxide by carbon dioxide. Small concentrations of carbon dioxide (1 to 2 per cent) in the presence of 50 per cent oxygen may also enhance the effectiveness of oxygen by increasing its movement from the blood to the tissues (Bohr effect).

Therapeutic Uses

Carbon dioxide-and-oxygen therapy has been reported to be of value during and after anesthesia, in the treatment of various asphyxias, electric shock, drowning, morphine poisoning, atelectasis neonatorum, postoperative atelectasis, epilepsy and dementia praecox and as an expectorant. The B.L.B. or Barach meter mask may be used, employing concentrations of 3 to 10 per cent carbon dioxide in oxygen.

Henderson and his associates³³⁻⁴⁷ first emphasized the value of carbon dioxide in depressed respiratory states, particularly those due to carbon monoxide poisoning. They⁴⁸⁻⁵³ extended its use to cardio-respiratory lesions characterized by dyspnea. Barach⁵⁴ decried this extended usage and proved its physiologic unsoundness. Other investigators questioned its value in asphyxia and atelectasis. Eastman, Dunn, and Kreiselman⁵⁵ made a study of the relative value of pure oxygen and of carbon dioxide mixtures in experimental resuscitation. Their work showed that oxygen is of the greatest importance in the treatment of asphyxia in dogs and that the effect of giving carbon dioxide in this condition is actually harmful. They concluded that the indiscriminate use of carbon dioxide should be guarded against in the resuscitation of the asphyxiated. Increasing evidence⁵⁶ favors the use of oxygen or helium-and-oxygen mixtures, with and without positive pressure, in the management of various types of atelectasis. He thought that the increased respiratory effort produced by carbon dioxide would be harmful with an obstructive respiratory picture, since it tended to increase the

intrathoracic negative pressure, thus producing pulmonary edema. This could be prevented by using oxygen or helium-and-oxygen mixtures, particularly with positive pressure. Martinez⁵⁷ also prefers pure oxygen to oxygen and carbon dioxide. He employed a pulmotor in a series of 500 infants and believed it to be the most effective method of resuscitating babies.

The Council on Pharmacy and Chemistry,⁵⁸ in an excellent review of the status of oxygen-and-carbon dioxide therapy, states that, since there has been no adequate evidence of a state of carbon dioxide deficiency of sufficient severity or frequency in clinical disease, the value of such therapy cannot be explained on a deficiency basis. Furthermore, no adequate evidence has yet been presented proving the value of such mixtures in the routine therapy of pneumonia or heart disease.

Considerable controversy still exists concerning the over-all value of carbon dioxide inhalation as an expectorant in pulmonary disease. Alison⁵⁹ used inhalations of 5 per cent carbon dioxide with oxygen in some cases of beginning pneumonia and bronchitis in children. He thought that the disease process was aborted through the removal of the mechanical blocking of the airways. Banyai⁶⁰ used inhalations of 10 per cent carbon dioxide in oxygen in cases of pulmonary tuberculosis. He observed that the increase in respiratory rate was followed by easier expectoration and a decrease of cough. Large amounts of sputum were raised by almost effortless expectoration. The sputum changed from a heavy, thick and tenacious type to a thin, serous and watery form. Banyai and Cadden⁶¹ more recently confirmed the value of carbon dioxide inhalation as an expectorant in pulmonary tuberculosis. They attribute its effectiveness to a powerful respiratory stimulating effect, which reflects itself in a stretching and dilatation of the bronchial tubes, powerful peristaltic movements of the bronchi and liquefaction of the exudate that stagnates in the bronchial tree. They stress its contraindication in recent pulmonary hemorrhage, in severe emphysema, in extensive pulmonary fibrosis without atelectasis, bronchiectasis or mucopurulent retention in the air passages, in acute plastic pleurisy and pleurisy with effusion and in hypertension. Campbell and Poulton⁶² encouraged the use of carbon dioxide and oxygen in the treatment of pneumonia.

Basch, Holinger and Poncher^{63, 64} made an exhaustively careful study of the physical and chemical properties of sputum, particularly the influence of drugs, steam, carbon dioxide and oxygen. They concluded that inhalations of steam are more effective than drugs in liquefying sputum. Inhalation of carbon dioxide serves as a most efficient expectorant. Such inhalations reduce the amount of sputum within the bronchial tree by stimulating resorption and render the remainder liquid, so that it is easily coughed up. They found the most efficient regimen

o be a combination of carbon dioxide, steam and expectorant drugs. The above observations of Allison, Banyai, Campbell and Poulton, and Basch et al. certainly favor the use of carbon dioxide inhalation as an expectorant. Nevertheless, one should use it only with a full appreciation of its contraindications as described previously by Basch et al., Eastman et al., Kane, Barach and others.

Barach⁶⁵ employs 5 to 15 per cent concentrations or the management of hiccoughs with considerable success. With higher concentrations the patient becomes drowsy and profoundly relaxed. He generally begins treatment with a 5 per cent concentration and increases it to 15 per cent for three to ten minutes at each treatment if the patient becomes refractory to the lower percentages.

Kornmüller⁶⁶ investigated the influence of 3 to 5 per cent carbon dioxide in oxygen inhalations on the electroencephalographic changes in patients with epilepsy or dementia praecox. The observations demonstrated that carbon dioxide may counteract these changes. He concluded that therapeutic effects may be expected from the use of carbon dioxide in these diseases and that the effects of tetrazol, insulin and electric-shock treatments may be partly due to the fact that they increase the carbon dioxide content of the brain and blood.

At altitudes above 35,000 feet the arterial saturation with oxygen falls rapidly, with associated symptoms of anoxemia, in spite of breathing pure oxygen. There has been considerable discussion whether the addition of carbon dioxide to the inspired air physiologically increases altitude tolerance in the aviator. Theoretically this is possible on the basis of its ability to increase the dissociation of oxyhemoglobin, to cause cerebral vasodilatation and to stimulate respiratory activity. Gibbs et al.⁶⁷ made a study of arterial and jugular blood and of brain function in normal men who breathed mixtures containing various percentages of oxygen and varying ratios of nitrogen and carbon dioxide. The addition of carbon dioxide to low-oxygen mixtures permitted maximal utilization of the available oxygen and the maintenance of normal brain function as seen in the electroencephalogram. Johnson et al.⁶⁸ studied the effects in dogs of adding carbon dioxide to oxygen-enriched atmospheres in low-pressure chambers. The addition of carbon dioxide corresponding to a tension of 14.3 mm. of mercury increased the minute ventilation by 39 per cent without any beneficial influence on the oxygen tension of the mixed venous blood. The authors concluded that such an added burden should be avoided in human beings when no benefit from carbon dioxide inhalations can be demonstrated.

WATER-VAPOR THERAPY

The principal value of water-vapor therapy is in the treatment of respiratory disease in which thick, tenacious mucopurulent secretions accumulate in the tracheobronchial tree and larynx. Thinner

tions may result from the high humidity of the inspired air, which reduces the loss of water from the mucosa, and expectoration is thus facilitated. Such therapy may be of life-saving value in croup, obstructive dyspnea and inhalation gas poisoning. Everyone is acquainted with the ancient steam kettle and the assortment of croup tents. More modern methods comprise the high-humidity room, humidified mask therapy and the humidified oxygen tent. The minimal allowable relative humidity is 75 per cent. This may be raised to the saturation point in the high-humidity room.⁶⁹ The Walton mechanical humidifier is an instrument that blows water vapor and fine droplets into the air by a fan and centrifugal force. No heat is evolved.

Holinger,⁷⁰ in discussing the therapy of acute laryngotracheal bronchitis, favors placing the patient in a room supersaturated with warm water vapor, the relative humidity reaching 90 per cent if possible. He also mentions briefly the use of oxygen, helium-and-oxygen mixtures, bronchoscopy, tracheotomy and the sulfonamides. No precise technic is described. His results appear good, but more data are necessary for proper evaluation.

It is doubtful whether tincture of benzoin employed in the simple steam humidifiers is of any value. Many believe it to be irritating. Following the suggestion of Healey,⁷¹ I have employed a mixture of menthol, camphor and eucalyptol in a milk-of-magnesia base. Such a mixture was objectively comfortable in a group of patients with inhalation gas poisoning and obstructive respiratory disease.⁷²

In employing oxygen therapy it is essential to ensure adequate water vapor. If one uses the catheter method, it is well to employ a simple water-bottle humidifier. Many prefer a diffusion-head inlet and a water-trap outlet type of humidifier. With the B.L.B. apparatus humidification may be desirable if high oxygen flows are used. Adequate water-vapor concentrations can be obtained with the use of the injector when employing the Barach-Eckman-Mofolomut mask. If higher humidity is desired, the injector may be removed and the water-bottle type of humidifier substituted. In using the oxygen tent it is difficult to maintain high humidity because the cooling system reduces the humidity. A moderate increase in humidity may be obtained by decreasing the temperature and increasing the circulation to maintain cooling. Davison⁷³ devised a method of connecting a Walton or Gilbert humidifier to the tent canopy, which is most effective, although not sparkproof. A sparkproof humidifier must be employed for use in high oxygen concentrations. This type of arrangement will probably be standard in the tent of the future.

ADMINISTRATION OF VAPORIZED SOLUTIONS

Bronchodilator and Vasoconstrictor Drugs

To the growing list of directive terms must be

system in terms of cargo, crew and ships, the oxygen diffusion gradient from the lungs to the tissue cells being represented by the flow of water from the Great Lakes to the sea.

General Clinical Use

It is of interest at this point to recall that Beddoes in 1795 was enthusiastic about oxygen as a universal panacea. Gradually, however, its use became discredited owing to lack of effective administration and understanding of the principles underlying its use. The employment of 40 to 50 per cent concentrations of oxygen in the treatment of war-gas poisoning and the resultant pulmonary edema again stimulated the application of oxygen therapy to clinical disease.

Various concentrations of oxygen have been successfully employed in pneumonia, pulmonary atelectasis, pulmonary fibrosis, emphysema, bronchial asthma, pulmonary embolism, pulmonary edema of varied etiology, asphyxia and resuscitation, anesthesia, altitude and compression work, circulatory failure, angina pectoris,¹¹² coronary thrombosis,¹¹³⁻¹¹⁵ anemias, abdominal distention,^{1, 116-118} peritonitis, anaerobic infections¹⁰¹ and migraine headaches¹¹⁹; following encephalography^{1, 120}; during fever therapy¹²¹; for peripheral vascular disease, shock of all origin and severe burns; preoperatively and postoperatively; in neurosurgery, obstetrics and traumatic and military surgery; and for a variety of miscellaneous diseases. Reviews of the value of oxygen inhalations in the therapy of cardiorespiratory disease may be found in reports by Barach.^{54, 103, 104, 107, 110} Reviews of the general use of oxygen therapy are given in the reports by Boothby and his associates.^{4, 13}

It is generally appreciated that the onset of anoxemia in a normal person occurs at an altitude of 10,000 to 11,000 feet. At such altitudes oxygen must be supplied. At altitudes above 30,000 feet the effect of lowered barometric pressure is added to that of oxygen want. This results in aeroembolism or aeroemphysema. This is essentially the same as the so-called "bends," or caisson disease, and the air emboli may lodge in any of the blood vessels of the brain, coronary vessels or other terminal vessels. The emboli are nitrogen bubbles released at low pressures, and nitrogen can be partially replaced by oxygen. Preflight oxygen breathing and the same continued throughout ascent and descent prevents these reactions. Flying per se has no effect on the cardiovascular system. The effects noted — electrocardiographic changes and so forth — are all due to the low oxygen or low barometric pressure at high altitudes and the mechanical effects of speed. The latter result from centrifugal force, and the pilot "sees black" in positive accelerations — cerebral anemia and splanchnic and extremity engorgement — and "sees red" in negative accelerations.

Mechanical devices may prevent or cure the latter, and oxygen the former.

Lovelace¹²² in a timely discussion stresses the fact that any clinical condition that causes anoxia is poorly tolerated at high altitudes. He describes the need for adequate oxygen and the difficulty of providing it in cases of concussion of the brain with and without skull fracture, in anemias and fulminating infections and in patients receiving sulfonamide drugs. He stresses the danger of expansion of gas in patients undergoing pneumothorax and in those with penetrating abdominal lesions at high altitudes, due to the lowered atmospheric pressure. In the latter cases the advisability of abdominal decompression with Wangensteen suction is suggested.

It is not enough to administer oxygen of the proper concentration to the anoxic patient. The entire transportation system must be analyzed and the deficiency corrected. Removal and treatment of the cause, supplemental shock therapy and restoration of blood plasma and hemoglobin may be just as important.

High Concentrations

Toxicity. Considerable controversy still exists as to the effects of high concentrations of oxygen on the epithelium of the lung. The earlier observations in animal experimentations demonstrated specific untoward effects generally characterized by pulmonary irritation, convulsions and a decreased metabolism (Barach,¹²³ Binger, Faulkner and Moore,¹²⁴ Smith et al.,¹²⁵ Shilling and Adams,¹²⁶ Behnke et al.¹²⁷ and Campbell^{128, 129}). It is now generally realized, however, that animals are more susceptible to oxygen poisoning than are human beings. Symptoms of oxygen toxicity were reported in normal persons rather than in patients with severe anoxia.

Occasional reports on toxicity in normal and sick persons appeared in the recent literature. Behnke and his associates^{130, 131} observed impairment of neuromuscular control and convulsions in normal subjects exposed to pure oxygen at 1 atmosphere of pressure for longer than six hours. Becker-Freyseng and Clamann¹³² made observations on 2 normal subjects who spent sixty-five hours in a gas-tight room containing 90 per cent oxygen. On the second day both felt uncomfortable, and in one there was a decrease in the vital capacity, associated with fever and a rapid pulse. On the third day one man felt especially ill and suffered from dyspnea, with a continuous fall in vital capacity. Behnke¹³¹ found that inhalation of 100 per cent oxygen to normal human subjects for seven hours produced substernal soreness and toxic effects. Moody and Howard¹³³ report a probable case of oxygen poisoning occurring in a two-year-old child acutely ill with lobar pneumonia. During one of her periods in the tent the patient developed convulsions, which subsided when

she was removed from the tent and returned shortly after she re-entered it. She was kept in the tent at frequent intervals for a period of six days. Unfortunately, no mention is made of exact oxygen-percentage determinations. It appears difficult to assify this case as one of oxygen poisoning.

Behnke¹³¹ stated that at atmospheric pressure pure oxygen is usually well tolerated by healthy persons over a period of six hours. An occasional healthy subject is particularly sensitive to it. The toxic signs and symptoms that may be observed at the higher atmospheric pressures are pallor, sweating, nausea, fatigue and irritability. These can be avoided by helium-oxygen breathing. Behnke and Arbrough¹³⁴ observed that at a depth of 500 feet, corresponding to a pressure of 16 atmospheres, a diver breathing a mixture of 80 per cent helium and 20 per cent oxygen felt nearly as well as at atmospheric pressure. In Behnke's experiments healthy subjects breathed pure oxygen at a pressure of 2 atmospheres for three hours without demonstrable harmful effects.

Although the cause of oxygen poisoning is unknown, Shaw, Behnke and Messer¹³⁵ demonstrated the remarkable relation between oxygen and carbon dioxide at increased atmospheric pressures. They showed in dogs at a constant pressure of 4 atmospheres that increasing the alveolar carbon dioxide tension was equivalent to raising the oxygen tension about 5 atmospheres. When the carbon dioxide tension was lowered by hyperventilation, the oxygen tension was decreased to about 3 atmospheres. At this high pressure the addition of carbon dioxide served to increase the toxicity of oxygen, whereas lowering the alveolar carbon dioxide tension by hyperventilation delayed or even prevented the onset of toxic oxygen symptoms.

Armstrong¹³⁶ further demonstrated the safety of high concentrations of oxygen in his studies on rabbits at decreased barometric pressures. With pure oxygen at a tension of 350 mm. of mercury — equivalent to an altitude of 20,000 feet — he failed to produce lung injury after an exposure of two hundred hours. This result has been repeatedly substantiated in aviators in more recent years.

Continuing their extensive studies on the effects of drugs on anoxia, Emerson and Van Liere¹³⁷ evolved a standard test to study the effects of drugs on the tolerance to anoxia in mice. They observed a slight increased tolerance to anoxia in mice pretreated with exposure to pure oxygen or to helium-and-oxygen mixtures. They did not, however, consider the mortality reduction in the control animals sufficient to conclude that the lethal effects of anoxia can be minimized with pretreatment inhalation of oxygen and helium-and-oxygen mixtures. They believed that their results could not be considered applicable to therapy in man without further investigation.

Clinical value. Under normal conditions increased concentration of oxygen has no effect on tissue function. Boothby and his associates^{4, 101, 102} demonstrated its value in the clinical anoxias. Inhalation of 70 to 100 per cent concentrations increases the partial pressure of oxygen in the lung, making it possible for the blood to absorb and transport a quantity in excess of the normal. The hemoglobin saturation can be raised from 96 to practically 100 per cent, and the oxygen in simple solution in the plasma from 0.3 cc. per 100 cc. of blood to a maximum of 2.2 cc. This represents a possible increase to as high as 15 per cent — supersaturation level — in the oxygen-carrying capacity of the blood throughout the circulatory system. This in turn produces a corresponding increase in the partial pressure available for the diffusion of oxygen from the blood into the tissues. In this connection, it will be recalled that Campbell and Poulton^{62, 137} demonstrated that the oxygen pressure in tissue is increased proportionately more than is the increase in oxygen content of the blood.

Evans¹³⁸ has for many years repeatedly described beneficial clinical results from so-called "100 per cent" oxygen in severe anoxia. Concentrations of 70 to 100 per cent should be used when lower concentrations are unsatisfactory. Boothby and his associates^{4, 13, 101} in extensive clinical observations proved the safety of high concentrations if used properly. They administered 90 to 100 per cent concentrations to approximately 800 patients for periods as long as forty-eight hours without any evidence of pulmonary irritation. They warned against continued administration for longer than forty-eight hours. Further clinical evidence showed that high concentrations can be used with safety with a mask apparatus for periods of two to five days. It is well to remember that mask therapy is really not continuous, inasmuch as the patient talks, eats or has the mask removed frequently for general nursing care.

In a recent paper Reinhard, Moore, Dubach and Wade¹³⁹ report on the effect of breathing 80 to 100 per cent oxygen in patients with sickle-cell anemia. They observed 3 patients at six different times, using the B.L.B. apparatus, with pure-oxygen flows without intermission for periods of eight to twenty days. They state: "No distinct toxic manifestations of the oxygen administration were noted except for inflammation and congestion of the mucous membranes of the upper respiratory passages. After oxygen was discontinued, 2 of the 3 patients became nauseated and had headache for twenty-four to forty-eight hours." My own clinical observations for periods of three to five days in patients with serious respiratory disease led to similar conclusions.

In closed respiratory chambers, such as the helium-and-oxygen hood apparatus, Barach^{9, 140} considers it inadvisable to use continuous oxygen

CASE 30151

PRESENTATION OF CASE

First admission. A fifty-year-old man entered the hospital because of a draining abdominal sinus.

The patient had been in apparent good health until about ten months before entry, when he developed generalized abdominal discomfort, most marked in the lower midline. This was accompanied by tenesmus, but an attempt to move the bowels was unsuccessful. He became slightly distended, but had no nausea or vomiting. He was operated on the second day of the illness. The details of the examination and operative findings were unknown, except that a lower right paramedian incision was made and a drain was left in place. This drained feces for four weeks and continued to do so, although in a much reduced volume. Postoperatively he had normal bowel movements by rectum with the aid of 30 cc. of mineral oil daily. He had had no distention, pain, or bloody, tarry or mucous stools. His appetite had been poor. He had lost 20 pounds during hospitalization, but his weight had remained constant since.

He had had typhoid fever two years before admission, was hospitalized for several weeks, but recovered without any sequelae.

Physical examination revealed a well-developed, moderately well-nourished man, with evidence of recent weight loss. The heart and lungs were negative. The abdomen was soft and nontender. There was a small draining sinus in the midportion of an otherwise well-healed, low, right paramedian incision.

The blood pressure was 120 systolic, 80 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood showed a red-cell count of 4,920,000, with 14.9 gm. of hemoglobin. The white-cell count was 8800. The urine was negative. Stools were guaiac negative. A blood Hinton test was negative.

A barium enema passed without delay from the rectum to the cecum. The sigmoid was spastic, and

*On leave of absence.

several diverticulums were visible in the distal sigmoid. The mucosa was swollen. Postevacuation films showed the sigmoid to be markedly irregular with a projection that was thought to be a fistulous tract. The remainder of the colon was contracted on the postevacuation film and displayed normal mucosal relief, except the ascending colon, which contained no barium. Re-examination of the colon showed marked irregularity of the wall of the sigmoid just above the rectosigmoid junction. There was no filling of the fistulous tract by enema. The cecum and ascending colon were spastic but filled symmetrically without filling defects. A lipiodol injection of the sinus tract showed ready passage of the dye to what appeared to be the sigmoid.

On the sixth hospital day a transverse colostomy was performed. Postoperatively the patient did well. The colostomy appeared to function well. On the third postoperative day he had a severe cramplike epigastric pain. Six hours later he vomited greenish, bitter material, and the vomiting persisted. The pain became intermittent. The abdomen was not distended, and peristalsis was normal. There were no masses or tenderness.

Plain films of the abdomen showed no dilated loops of bowel, but there was some gas scattered through the colon. At the level of the second lumbar interspace, there was a small round area of gas which was thought to be in the small intestine. Just above this a rounded area of increased density measuring 3.4 cm. was seen. This had a rather smooth margin.

A Miller-Abbott tube was passed. He had a good bowel movement through the colostomy opening with complete relief of symptoms. The Miller-Abbott tube was removed, and he was discharged home to return for another operation.

Second admission (twenty-four days later). Following discharge the patient had a bout of diarrhea lasting two or three days but was otherwise asymptomatic. His weight had remained essentially the same.

Physical examination was as before.

Examination of the blood showed a hemoglobin of 13.6 gm.

On the third hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. CARROLL C. MILLER: When the patient was admitted for the first time, he presented at first glance a perfectly definite and typical picture. If we were not for two complicating details, — namely, the gastrointestinal upset following the first operation and the visualization of a peculiar mass in the abdomen following this episode, either or both of which may or may not have anything to do with the final diagnosis, — it would be relatively easy to predict what was found at the second operation and the patient's subsequent course.

Let us, at the start, discuss the more likely underlying diagnosis. We see in the report and on the films that there was definite diverticulosis and probably diverticulitis of the sigmoid. When the patient first became ill, he complained of low abdominal pain, together with bowel tenesmus, difficult defecation and abdominal distention, but no nausea or vomiting. All these details are perfectly consistent with a diagnosis of diverticulitis in a middle-aged man. One aspect of the picture is slightly unusual. The onset was apparently abrupt, without the usual monitory signs of a disturbance in the lower bowel. People with diverticulitis frequently complain of difficulty in moving their bowels, tenesmus, and, occasionally, the passage of small amounts of stool over a period of some months or years. It is conceivable, however, that a bland type of diverticulosis may exist up until the time when a combination of physical circumstances arises to break off a diverticulum, seal up an infection in it and initiate an inflammatory process that may lead to involve bowel wall and structures around the bowel. All that can occur in the course of a few days, presenting a picture that simulates a combination of low intestinal obstruction and peritonitis.

This is apparently what the first operator thought when he made his first incision. The possibility of acute appendicitis should not have been given much consideration because of the location of the most marked pain and the absence of nausea and vomiting. No mention is made of previous symptoms that could be attributed to a chronicolecystitis or cholelithiasis and that might contribute to the diagnosis we are attempting to establish.

We have, therefore, a man who, on first admission to this hospital, presented a story and completely satisfactory x-ray evidence of a subsided inflammatory reaction in the lower abdomen or pelvis, with establishment of a fecal fistula communicating with the sigmoid. In the x-ray films the presence of diverticula, the spasm and the irregularity of the lumen of the sigmoid substantiate such a diagnosis. The surgeon who performed the first operation in this hospital evidently felt the same way and subsequently performed a transverse colostomy in preparation for a subsequent exploration, with a view to ligating the fistula and removing the diseased bowel.

The intestinal complication occurring on the third postoperative day may have been due to an inflammatory reaction around the site of the transverse colostomy, causing a subacute intestinal obstruction. At that time the second complicating picture—namely, the flat abdominal

—this mass apparently was not visible in any of the previous films. It may have been obscured by some other denser structure and at that particular moment may have become obvious. I am

sure that I cannot guess what it was. One would like to postulate a gallstone that had eroded from the gall bladder into the small intestine and caused intestinal obstruction, but this mass was unusually large and it is unlikely that such a gallstone would cause no further trouble. A gallstone of such size would undoubtedly have great difficulty in passing the ileocecal valve and therefore would cause further obstruction, which the patient did not have. We are not told and cannot be sure where the mass lay in relation to the lumen of the bowel. It is conceivable that this was a scybalum of barium lasting over from the previous barium enema, but its density in the x-ray film does not appear to be that of residual barium. Consequently, although I am much perplexed by the appearance of this phenomenon, I cannot believe that it had anything directly to do with the patient's subsequent condition.

When the patient re-entered this hospital he was apparently in good condition and ready for the operation that had been planned. I am a little surprised that it was done so soon after the first, for I should suspect that insufficient time had elapsed to allow the inflamed sigmoid to become suitable for surgery. I should suppose that there was still induration with adhesions in the lower abdomen and pelvis, making exploration and resection difficult. My final diagnosis is diverticulitis of the sigmoid, with fecal fistula.

CLINICAL DIAGNOSIS

Diverticulitis of sigmoid, with sinus tract.

DR. MILLER'S DIAGNOSIS

Diverticulitis of sigmoid, with fecal fistula.

ANATOMICAL DIAGNOSES

Diverticulitis of sigmoid, with perforation.
Peritonitis, acute and chronic, localized, with matting of loops of small intestine.

Diverticulosis of sigmoid.

Meckel's diverticulum.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: At operation Dr. Arthur W. Allen found many coils of matted small intestine adherent to the anterior abdominal wall at a point midway between the symphysis and the umbilicus, just to the right of the midline. The sigmoid was completely collapsed and was drawn over into this mass of matted small bowel, which corresponded to the site of the fistula. When these loops were dissected free it was found that a Meckel's diverticulum, measuring 6 cm., was in the center of the mass. About 50 cm. of ileum, including the diverticulum, was resected, and a side-to-side anastomosis was performed. Then the sigmoid was resected with an end-to-end anastomosis.

When we received the specimen there were two small perforations of the ileum about 4 cm. from the

Meckel's diverticulum. These could have been made in dissecting away the adhesions or may have been produced by the localized peritonitis in the region of the fistula. The Meckel's diverticulum showed no evidence of intrinsic inflammation. The sigmoid, however, was markedly thickened and covered with a patch of fibrinous exudate, in the center of which was a small perforation 2 mm. in diameter that connected with a long diverticulum. This diverticulum was inflamed, and appeared to be the primary source of infection. In addition there were many noninflamed diverticula throughout the specimen.

Three weeks later the original colostomy opening was closed; the ends of the colon were resected, and an open end-to-end anastomosis was performed.

CASE 30152

PRESENTATION OF CASE

A seventy-nine-year-old retired factory manager entered the hospital because of persistent cough.

The patient had been in excellent health until six months before admission, when without antecedent upper respiratory infection he developed a paroxysmal cough productive of a small amount of thick, nonodorous, greenish sputum. This persisted until about six weeks before admission, when the amount of sputum increased to several tablespoonfuls daily. He developed a "smoky feeling" under the sternum at the level of the sixth rib, without definite pain. He had had no hemoptysis, chills, fever or weight loss. An x-ray film of the chest, taken two weeks before entry showed slight enlargement of the heart downward and to the left. The lower part of the right lung field was less radiant than normal. In the lateral view the outline of the middle lobe was easily seen, and its position corresponded to the area of fullness in the right lower chest. The interlobar septums were moderately thickened. The lung fields were otherwise clear.

The patient had been extremely active until six years before the onset of his present illness, when he was advised by his physician to "take it easy." Two or three years later he noticed shortness of breath on climbing two flights of stairs.

Physical examination showed a well-developed, well-nourished man. He was distressed by frequent cough. The trachea was in the midline. There was dullness posteriorly over the right clavicle. The breath sounds were increased and well transmitted. Many moist inspiratory and expiratory rales were heard over the right middle and upper lung fields. There was a loud moist wheeze over the whole right lower chest. The heart was slightly enlarged; the sounds were regular but faint. Examination was otherwise negative.

The blood pressure was 158 systolic, 88 diastolic. The temperature was 99.4°F., the pulse 85, and the respirations 24.

Examination of the blood showed a hemoglobin of 14.9 gm. The white-cell count was 6800, with 6 per cent neutrophils. The urine was normal. A blood Hinton test was negative. Another x-ray film of the chest, taken two weeks after the previous examination, revealed some increase in the size and density of the lesion on the right. There was no respiratory movement of the right half of the diaphragm. The outline of the diaphragm was irregular, and the right costophrenic sinus was shallow. The pleura was somewhat thickened along the axillary border.

On the third hospital day a bronchoscopy was performed.

DIFFERENTIAL DIAGNOSIS

DR. HELEN PITTMAN: May we see the x-ray films?

DR. MILFORD SCHULZ: The right middle lobe does not seem to me to be particularly decreased in size. I believe this represents its outline. There is hazy increased density overlying the right lower chest.

DR. PITTMAN: What about the pleural thickening?

DR. SCHULZ: There is a little on the right, and I wonder if the increase in density on the right side as compared with that on the left might not all be due to the thickened pleura.

DR. PITTMAN: What about the position of the diaphragm on the left?

DR. SCHULZ: It is elevated. A true paresis of the left half of the diaphragm, which would have been noticed fluoroscopically, was not observed.

DR. PITTMAN: There was true paresis on the right?

DR. SCHULZ: That must be accepted as the fluoroscopist's observation.

DR. PITTMAN: I do not believe that these films throw much light on the subject, and I am rather disappointed.

This seventy-nine-year-old man was in excellent health until the age of seventy-three, when he was advised to "take it easy." He had shortness of breath, which does not seem out of order for someone who is that old.

His illness began six months previously, when, without any prodromal symptoms and without any respiratory symptoms, he suddenly began to have paroxysmal cough and raised small amounts of sputum; this continued for a matter of four months or so. Then, for no apparent reason, the sputum increased in amount and became thick and yellowish and the patient developed a peculiar feeling, a "smoky" feeling, — whatever that means, — under the sternum at the level of the sixth rib. He did not have pain, did not spit blood and did not have chills, fever or weight loss. In other words, the only clue is that he had productive cough.

Physical examination showed dullness posteriorly on the right, over the right clavicle, which I suppose means the right apex posteriorly. "Breath sounds were increased and well transmitted." They usually are in that region of the chest. I do not believe that

that means so much. The loud moist wheeze over the right lower chest is the first thing that gives a localizing clue; the unilateral wheeze I interpret as a definite indication of partial obstruction of one bronchus on the right side — the middle or lower lobe, I do not know which. I should guess the middle lobe, but from the description and from these films I cannot be sure. He had slight fever, which seems noncontributory. He had no anemia and no leukocytosis, and the white count was normal, with a low normal percentage of neutrophils.

So we have here a man with a cough who had nothing to go with the cough and no evidence of infection beyond a temperature of 99.4°F. At no time had he had bleeding, pain, or anything that would lead one to suspect carcinoma, and of all the things that should make one suspect carcinoma, bleeding is the most significant. The absence of bleeding is important, but not necessarily diagnostic.

Then we come to the next positive finding, — the area of increased density in the right lower chest, — and I think that the only other definite positive finding is that there was no respiratory movement of the right half of the diaphragm. Why was there no respiratory movement of the diaphragm on the right? I do not know. We have nothing from the history, physical examination or x-ray findings to suggest that there was a process involving the phrenic nerve on that side. It is hard to think that he could have an aortic aneurysm involving the phrenic nerve with as little to go on as this.

The next point is, Did he have an acute pleurisy on the right side, which would cause immobility of the diaphragm? He had had no pain at any time, and the evidence of real pleurisy is extremely slim. I am sure that the immobility of the right leaf of the diaphragm is one of the most important findings, but there is not enough evidence to say with any certainty what caused it. So we are left with the area in the right lower chest. Whether these x-ray changes were secondary to the paralysis of the diaphragm, I do not know. I rather doubt it, because he was producing large amounts of sputum, and I am assuming that he had something in the bronchus causing partial obstruction, which was giving him this wheeze. We have no way of tying that up with the diaphragm unless we assume carcinoma, but there is no evidence on which one is justified in saying that this man had carcinoma.

How about a bronchial adenoma? I do not believe that we have enough evidence to postulate an adenoma, although that is one of the things that has to be seriously considered.

How about a nonopaque foreign body? It will cause a wheeze, but it is always associated with infection, and that is true everywhere else in the body. I do not see that we are justified in making that diagnosis.

Tuberculosis always has to be thought of, but again there is not much to go on. It is an unusual

site for tuberculosis, although that does not rule it out. In a seventy-nine-year-old man I should certainly expect more evidence of old tuberculosis elsewhere in the chest than we have in this x-ray film.

Is there enough evidence of old pleural infection to think he could have had at some time empyema and a bronchial fistula? There is absolutely no evidence for that, and again if it were active enough to have suddenly broken into a bronchus, with the patient evacuating empyema fluid out through his mouth, I should expect signs of infection and not an odorless sputum, although that is possible.

So I am left with a series of entirely unsatisfactory explanations for this man's condition. Because he had definite physical signs on the right side, and because he did have a wheeze heard only on the right side, I am going to cling to something in the bronchus, causing partial obstruction, as the most probable lesion. And because I have no evidence that satisfies me for carcinoma or for tuberculosis, I am going to call it adenoma, but with little faith.

DR. EDWARD B. BENEDET: We did a bronchoscopy with a preliminary diagnosis of carcinoma, believing that in a patient of this age carcinoma was the most likely diagnosis. We did not pay enough attention to the fact that the patient had not lost any weight. Bronchoscopy showed widening and partial fixation of the carina, and a nodular outcropping in the right-stem bronchus causing partial obstruction of the right middle and lower lobes.

CLINICAL DIAGNOSIS

Carcinoma of the lung.

DR. PITTMAN'S DIAGNOSIS

Bronchial adenoma.

ANATOMICAL DIAGNOSIS

Tuberculosis of the bronchus.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: From the appearance that Dr. Benedict has just described it was thought that the diagnosis was probably carcinoma. The material that we received showed a granulomatous process, with one suggestive tubercle, although we did not have enough material to make a positive diagnosis of tuberculosis. It certainly looked suspicious of tuberculosis, however, and this was confirmed by examination of the sputum, which contained numerous tubercle bacilli. The patient therefore had tuberculous stenosis of the bronchus, probably with involvement of the mediastinal lymph nodes.

DR. BENEDET: I have tried to keep in touch with this patient, and from hearsay, I have learned that he is doing well. He is going to an osteopath.

DR. CASTLEMAN: Are organisms still present in his sputum?

DR. BENEDET: I do not believe that his sputum has recently been examined.

PUBLIC OPINION AND COMPULSORY SICKNESS INSURANCE

THE Wagner-Murray-Dingell Bill has provoked a great deal of discussion among physicians. Numerous editorials and articles have appeared in medical journals, and it is fair to assume that most doctors have thought somewhat about the significance of Title IX of the bill and know how most of their colleagues react to it. On the other hand, what other professional men and laymen think about the medical aspects of the bill is less clear. It is known that soon after the bill was introduced into Congress, the leaders of both national labor organizations issued statements strongly supporting it.

Furthermore, editorials have appeared in the press both for and against this proposed legislation.

Some time ago the American Bar Association appointed a committee to study the medical provisions of the bill, and its report, which was reprinted in the March 11 issue of the *Journal of the American Medical Association*, is well worth reading. The preamble to its conclusion is as follows:

The American Bar Association is limited to an expression of opinion and judgment with respect to those fields which relate to the administration of justice and which directly affect the safeguards and protection of the rights and liberties of the citizens of this country. Under normal circumstances, therefore, it is not the function of this association to attempt to influence substantive legislation by the Congress of the United States. But when, under the pretext of the general welfare, legislation is proposed in Congress which either inadvertently or with deliberate subtlety constitutes a direct attack on the rights and liberties of the citizens of this country, it becomes the duty of this association actively to voice its objections. . . .

It is apparent that the main objections of the committee are based on the powers vested in the Surgeon General of the United States Public Health Service, without machinery of appeal, and the vicious system of federal control, without safeguarding the rights of patients, hospitals and physicians.

Another important point of view is furnished by a comprehensive survey recently made for the National Physicians Committee and published in a booklet entitled *The American People*. This should be read and studied by every physician and should be passed along to his patients and friends. It is quite evident from this survey that the majority (84 per cent) of the people, including industrial workers, are unwilling to pay the cost of a federal health system, and that 68 per cent will have nothing to do with it regardless of cost. A significant fact to be gleaned from the survey, however, is that 63 per cent of the people *do* want some form of prepayment sickness insurance. This warning cannot be ignored.

The extraordinary success of the Blue Cross, both in Massachusetts and elsewhere, can leave no doubt in anyone's mind that voluntary organizations are able to provide adequate hospital care if they are well administered. Furthermore, it seems likely that voluntary insurance schemes for covering the costs of medical care will prove to be equally effective. Many such plans are already in operation, including

the Blue Shield, sponsored by the Massachusetts Medical Society, but at the moment they do not cover the needs of enough people. It is evident that the laity do not want compulsory health insurance sponsored by the Government. 85 per cent of the people believe that their physicians have a personal interest in them and that this would be lost under federal control. Nonmedical people are looking to the medical profession for leadership in providing complete prepayment sickness insurance on a voluntary basis.

acute entzündliche Knochenatrophie [Concerning Acute Inflammatory Atrophy of Bone], published in the *Archiv für klinische Chirurgie* (62: 147-156, 1900). A portion of the translation follows:

The bone atrophy that occurs in association with acute inflammatory affections of the bones and joints occupies a special place in my opinion and is essentially different from the simple atrophy of disuse. In the latter, for example, atrophy occurs to any considerable extent only if the functional stimulus has been lacking over a long period of time — at least a few months, — whereas in what I have referred to as acute inflammatory affections of the bones and joints a significant degree of atrophy takes place in a remarkably short period of time, not only indeed in the bones directly involved, but also in the neighboring bony structures that are functionally related to the diseased bone.

FORT DEVENS CONFERENCE ON MILITARY SURGERY

THE Conference on Military Surgery presented by the surgical staff of the Lovell General Hospital at Fort Devens on March 30 was attended by 46 medical officers of the United States Navy as well as by 127 civilian physicians from various parts of New England, the total attendance being 284. The conference was an outstanding success and clearly demonstrated the high grade of clinical and laboratory procedures used by the armed forces. The subjects of penicillin therapy and reconstruction of intestinal wounds and a motion picture study of the rehabilitation of the wounded soldier were of especial interest.

Such conferences are the complement of the monthly graduate courses presented by civilian instructors under the auspices of the New England Committee for Wartime Graduate Medical Meetings at twenty different stations of the Army and Navy throughout New England, beginning last November.

It is of further interest to know that both the Army and Navy plan to have exhibits at the annual meeting of the Massachusetts Medical Society in May. Details about these exhibits will be published in the final program.

MASSACHUSETTS MEDICAL SOCIETY COMMITTEE ON LEGISLATION

Public hearings will be held in various cities of the Commonwealth to study the possibility and desirability of a system of cash payments to persons who become unemployed because of illness or accident not otherwise covered under the Workmen's Compensation Act.

The Massachusetts Legislature, by Chapter 54 of the Resolves of 1943, placed the responsibility of the study of such a program with the State Advisory Council of the Massachusetts Division of Employment Security. Public hearings, conducted by this body, are scheduled as follows:

Lawrence	April 17	Council Chambers City Hall 2 30 p.m. and 7 30 p.m.
Fall River	April 20	Council Chambers, City Hall 2 30 p.m.
New Bedford	April 20	Room 20 City Hall 7 30 p.m.
Springfield	April 26	Room 212, City Hall 2 30 p.m. and 7 30 p.m.
Pittsfield	April 27	Council Chambers City Hall 2 30 p.m. and 7 30 p.m.
Worcester	April 28	Council Chambers City Hall 2 30 p.m. and 7 30 p.m.
Boston	May 1	Lord Hall 15 Ashburton Place 2 30 p.m. and 7 30 p.m.

The Advisory Council, through these hearings, is seeking to obtain the reactions of the people of Massachusetts as to the need of such a program. The following questions are pertinent: (1) Is there the need of a compulsory program of cash benefits for sickness or nonindustrial accidents in the Commonwealth of Massachusetts? (2) If such a program should be adopted, should it become a part of the present unemployment compensation program or is it in fact an inseparable part of a general health program which, if adopted, should be administered by some other department, such as the Department of Public Health? Is the country ready for a general health program? (3) If desirable to adopt a state system of sickness benefits, how should it be financed? Can the Massachusetts worker afford to pay for any further expansion of the social security program?

MEDICAL EPONYM

SUDECK'S ATROPHY

Dr Paul Sudeck (b. 1866), professor of surgery at Hamburg, was the author of a paper, "Ueber die

Should the system be financed by employee or worker contributions only? By employer contributions only? By a combination of both? Or by a combination of employer, employee and state contributions? (4) Is such a program of a social or public interest? If social, should not all the residents of the Commonwealth be included in the program instead of confining the same to workers covered under the present unemployment compensation program?

The above is an outline of the type of questions involved and to which the Advisory Council wishes to obtain an expression of opinion on the part of the general public prior to making its report to the General Court. The members of the State Advisory Council of the Massachusetts Division of Employment Security are Morris B. Lambie, chairman, Henry Cloutier, Joseph Cabral, Mary M. Riley, Fred W. Steele and Alfred E. Rankin.

All parties interested in this matter are cordially invited to attend.

BRAINARD F. CONLEY, *Chairman*

DEATHS

COLBURN — Frederick W. Colburn, M.D., of Boston, died April 9. He was in his seventy-fourth year.

Dr. Colburn received his degree from the Boston University School of Medicine in 1897. In 1899 and 1900 he did postgraduate work at Vienna, Austria, and Halle, Germany. Shortly after his return to Boston, he became assistant instructor of otology at the Boston University School of Medicine. At the time of his death he was professor emeritus. He joined the staff of the Massachusetts Memorial Hospitals as assistant aural surgeon and later advanced to surgeon-in-chief of the Ear, Nose and Throat Department. He was a member of the Massachusetts Medical Society, the American Medical Association and the American Homeopathic Ophthalmological, Otological and Laryngological Society and a fellow of the American College of Surgeons.

A daughter, two sons and a brother survive.

GLEASON — Edward F. Gleason, M.D., of Boston, died April 9. He was in his seventy-sixth year.

Dr. Gleason received his degree from the University of Vermont College of Medicine in 1899. He studied surgery at the University of Vienna and on his return established practice in Boston. He was one of the first members of the staff at Cape Cod Hospital, Hyannis, which was founded in 1920. He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow, two daughters and two sisters survive.

LEMAIRE — Willard W. Lemaire, M.D., of Worcester, died January 27. He was in his sixty-sixth year.

Dr. Lemaire received his degree from the University of Vermont College of Medicine in 1902. He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow, a son and a daughter survive.

MERRICK — Francis H. Merrick, M.D., of Boston, died January 17. He was in his thirty-eighth year.

Dr. Merrick received his degree from Boston University School of Medicine in 1933. He served on the staffs of the Boston City and St. Elizabeth's hospitals. He was a member of the Massachusetts Medical Society and the American Medical Association.

PARKS — Silas H. Parks, M.D., of Great Barrington, died November 7. He was in his eighty-third year.

Dr. Parks received his degree from the Albany Medical College in 1885. He was a member of the Massachusetts Medical Society and the American Medical Association.

MISCELLANY

TUBERCULIN TEST, X-RAY AND OTHER DIAGNOSTIC AIDS

To diagnose the greatest possible percentage of unsuspected cases of tuberculosis, to place these people under immediate and adequate care, to render them and the community safe from further spread of their disease, to rehabilitate every patient into a productive member of society — these are our tasks. Diagnostic procedures that guarantee the maximum return in case finding are those that safely apply the clinical lessons of the past to the pressing problems of the present. No thorough clinician relies exclusively on a solitary diagnostic aid, even when circumstances strongly tempt him to do so. These points are clearly brought out in the following paper (Myers, J. A. Tuberculin test, x-ray and other diagnostic aids. *Journal-Lancet* April, 1944).

There is now a strong tendency to "diagnose" tuberculosis by short-cut and sometimes slipshod methods. Recently, a few physicians were asked how they would proceed to find all the tuberculosis among the population of an entire industry or county. One stated that increased red-cell sedimentation rate would ferret out all cases. Another would discover them by finding acid-fast bacilli in their sputums. Still another would employ only x-ray-film inspection of their chests. Other similar methods were offered. Each physician presented an important phase of an examination, but not one of them was adequate. To achieve a satisfactory diagnosis each one of this group of physicians would have to examine a given individual in his own way, then pool his findings with those of his colleagues — a wasteful and illogical procedure.

There can be no tuberculosis in the absence of tubercle bacilli; therefore, the first phase of an examination is to determine whether bacilli are present. This can be done by the tuberculin test, which is accurate and specific except in the first few weeks after infection occurs, and in acutely ill and terminal cases. Other failures are usually due to the use of impotent tuberculin or to improper administration. Under proper conditions, then, a nonreactor to tuberculin can be told that he does not have living tubercle bacilli in his body. On the other hand, a reactor has at least primary lesions that contain living tubercle bacilli. Exceptionally, and only when all bacilli die, allergy persists for a time, then wanes and disappears. Inasmuch as primary tuberculosis is a prerequisite for the clinical forms, it is of extreme importance to know whether it is present. The tuberculin test provides this information with uncanny accuracy. With the exceptions mentioned, it is with great rarity that the person with clinical tuberculosis fails to react to tuberculin.

The next phase of the examination consists of inspecting the chests of all adult reactors with the x-ray. On the ordinary film 25 per cent of the lung parenchyma is obstructed from view by shadows of such parts as the heart and diaphragm. Films fail to reveal evidence of primary tuberculosis in 70 to 80 per cent of the persons in whom it actually is present. So, too, many lesions of the reinfection type, because of their size and consistence, escape detection. It is a frequent experience to view a film that appears clear, yet one of the same chest a few months later reveals evidence of disease. Therefore, adult tuberculin reactors whose lungs appear normal should have films at least annually.

After tuberculous lesions of the reinfection type attain macroscopic proportions, x-ray inspection is by far the best method of detecting their locations when they are in that part of the lung which is visualized; indeed, they cast shadows on an average of two or three years before they cause significant symptoms. Final diagnoses, however, should never be made from x-ray shadows, since those cast by tuberculous lesions may be indistinguishable from those of numerous other pulmonary diseases, such as sarcoidosis, silicosis, malignant tumor, fungus infections, abscess and pneumonia. When a lesion is found, its etiology can usually be determined by other methods.

The present, widely used procedure that begins with x-ray inspection of the chests of large groups of adults is laudable, provided it does not end there. All concerned must be informed that x-ray inspection is done with the unaided eyes and reveals nothing but macroscopic lesions, that one fourth of the lung parenchyma is obstructed from view by shadows of other parts and that final diagnoses cannot be made with accuracy from x-ray shadows. Thus, the tuberculin test screens out those persons who have living tubercle bacilli in their bodies, and from them the x-ray screens out those who have gross lesions that may be tuberculous. Neither nor both procedures constitute an adequate examination.

To determine whether a demonstrable lesion is tuberculous one must seek tubercle bacilli in material obtained from it. Among patients with extensive tuberculous lesions these are usually promptly recovered from the sputum. When bacilli are not found in more than one of several specimens, or if no sputum is present, gastric lavage may reveal their presence. Visualizing acid-fast organisms by the aid of the microscope may not be sufficient because of laboratory errors and also because nonpathogenic, acid-fast bacilli are sometimes found in the sputum and gastric contents; therefore, their pathogenicity should be determined by culture on an artificial medium or by animal inoculation. In the event tubercle bacilli or other pathogenic organisms are not recovered, one should observe frequently new x-ray films to determine whether abnormal shadows persist or any significant changes occur in or around them. Among persons beyond thirty-five years, however, one should avoid delay, as the lesion may be malignant. In such cases the bronchoscopist should be consulted, as he may promptly reveal the etiology.

There is no more deplorable practice than to have tuberculin tests administered and x-ray films prepared, after which the physician makes diagnoses without seeing the subject and completing the examination. The subject should always be interviewed by the physician. Although most persons have no symptoms for an average of two or three years after the disease can be located, and practically none of those with primary tuberculosis give histories of significant illness, the tuberculin reactors whose chest films are entirely clear may reflect symptoms caused by extrathoracic tuberculosis. In deed, acute conditions, such as meningitis and miliary disease, or chronic lesions in such parts as the kidneys, pelvic organs, and bones and joints may be developing.

Following the interview, even though no significant evidence is obtained, the remainder of the traditional physical examination should be made, since significant pulmonary signs may be elicited from lesions located near the periphery or in parts of the lungs not visualized by x-ray, moreover, lesions may be found during the scrutiny of extrathoracic regions.

To summarize: Tuberculosis begins when the tubercle bacilli first enter the human body and are focalized in microscopic lesions. At that stage the disease may be dormant or may even disappear. Again, it may undergo exacerbations and remissions resulting in every form of clinical tuberculosis to which the human body is heir. The physician can diagnose tuberculosis within a few weeks after the first invasion of tubercle bacilli, and he can detect most of the subsequent lesions with considerable promptness. Either to diagnose tuberculosis when it does not exist or to fail to find it when it is present, is inexcusable. Nearly all errors in diagnosis are due to short-cut or slipshod methods and may be avoided by employing every phase of a complete examination — Reprinted from *Tuberculosis Abstracts* (April, 1944)

THE WHITE PAPER ON THE NATIONAL HEALTH SERVICE

The following statement was recently released by the Information Division, British Information Services, 30 Rockefeller Plaza, New York City.

* * *

The White Paper on National Health Service published by the Ministry of Health and the Department of State for Scotland on February 17, 1944, is the latest in a series of far-reaching plans for the social development of Great Britain. Its aim is to fill the gaps in Britain's already extensive medical services and "to make a complete range of medical services of the best quality available to all."

The White Paper represents the considered opinion of the Government, but not its final decision. The proposals will be freely examined and discussed in Parliament and throughout the country. Discussions will be

held with representatives of the medical profession, local authorities, voluntary hospitals, pharmacists and so forth. In the light of the constructive criticisms thus obtained, legislation will be proposed later in the year. Copies of the White Paper are being sent to 50,000 doctors practicing in Great Britain, or serving in the armed forces, and their comments on the scheme are invited.

This Paper is not to be confused with the White Paper on social insurance (arising out of the Beveridge Report), which is still in preparation. It does, however, aim at the fulfilment of Assumption B of the Beveridge Report — the assumption of comprehensive health and rehabilitation services for all as a basis for comprehensive social insurance.

Medical Facilities

Complete free medical facilities, general and specialist, are to be easily available to all. These will include the following:

General medical care. General medical care will be supplied by a general practitioner for every man, woman and child. Free choice for both patient and doctor is to be preserved. As under the present National Health Insurance scheme, patients will be free to employ any doctor privately, if they wish, and doctors will be free to have a private as well as a public

... able to choose their respect to preserve that efficient and

... free to work either, as now, in their own surgeries or in grouped practices, similar to present privately arranged partnerships, or in health centers. These centers, which are to be increased and developed to the fullest extent, would

... patients be free to choose their own doctor, who would visit them in their homes if necessary

... more expensive medical work done by pharmacists

... as to be ordained hospital

... essential part of national

... invited to take part in the national scheme under their own management, but under compulsion to observe the general conditions. In return they will receive certain service payments in accord with centrally determined scales, but less in amount than the actual cost of the services rendered. (If the voluntary hospitals are to be maintained they must continue to rely largely on their own resources and private benefaction.) Certain other payments will also be made to the hospitals from the Central Fund in respect of their help in the scheme, and it is suggested that the hospitals may wish to make one fund of these, from which allotments could be made to individual hospitals according to their need.

There will be no interference with the internal management of voluntary hospitals — no surrender of their independence or change in their status.

All hospitals will be visited and inspected by experts who will keep

... will be available through health centers or in the home

... of consultants and to spread remuneration and conditions

... hospitals, although group practices and health centers will also offer more specialized treatment than the average general practitioner can offer today.

Maternity and child welfare services. All the present institutional arrangements, in hospitals and maternity homes, for maternity cases will

Domestic medicine and nursing. Both the new Education Bill and the present

School medical service. Both the new Education Bill and the present White Paper envisage that the education authorities will retain the function of inspecting school children and encouraging necessary medical treatment. When the new health service is inaugurated, however, children as well as adults will look to it for medical treatment.

Tuberculosis dispensaries, cancer diagnostic centers and mental clinics. All these will be outpatient activities of the reformed hospital and con-

... service of this type will be taken to increase the supply in young people and expect-

... will be to ensure that those ill be able to obtain it with out charge. The scheme will probably be administered by county and county-borough councils.

Organization and Remuneration of General Practitioners

There will be no compulsion on doctors to join the National Health Service, but it is expected that the great majority will do so. The great majority have joined in the present National Health Insurance scheme. Doctors who take on a public practice will be free to have a private practice also. The numbers of private patients will inevitably be reduced, however, as equally good treatment and care will be available free in the public service.

In order to ensure equality of conditions of public service throughout the country, it is proposed that the general practitioner service will, in the main, be centrally organized.

The Central Medical Board, appointed by the Minister of Health, will be responsible for much of the administration of the service and will act as "employer" of doctors who take part in the service. It is with the board that doctors will enter into contract. (Doctors in health cen-

ters will enter into a three-sided contract with the Central Medical Board and the local authority.)

As described above, doctors will be free to join the public service either in separate practices, in group-practices or in health centers. It is proposed that young doctors fresh to the service should start their work as apprentices to more experienced general practitioners.

The proposals of the White Paper as regards remuneration of doctors do not envisage a system under which all doctors engaged on public service would be paid by salary. It is suggested instead that, whereas doctors in health centers should be salaried workers in order to prevent any competition for patients, those in separate practices should normally be paid according to the number of public patients in their care — a capitation system similar to that now used under the National Health Insurance scheme. Doctors in grouped practices other than health centers will be able to choose which method they prefer. It is proposed that the maximum number of patients that any one doctor may care for should be regulated. A doctor having a private as well as a public practice will be allowed fewer public patients, and thus less public remuneration.

Although there will be no interference with doctors who wish to go on practicing where they are and to take part in the local public service, there will be regulation of the entry of doctors into new practices, in order to ensure reasonable distribution throughout the country. Doctors wishing to set up a new, or take over an existing, public practice will have to obtain the consent of the Central Medical Board. If the area is "over-doctored," permission may be refused. The Joint Authority will be responsible for the integration of general medical practice within the general area plan — including arrangements for the numbers and distribution of doctors and their liaison with hospital, specialist, clinic and other services in the area.

The sale of practices will clearly be affected by the regulation of doctors entering new practices. A doctor giving up his practice in an "over-doctored" area may find that the board will not permit his practice to be purchased. Again, practices within a health center will not be saleable. Thus a doctor who leaves a private practice for a health center will be exchanging a practice that he can sell for a practice that he will be debarred from selling.

To remedy these cases of hardship a scheme of compensation for practices that lose their value and a superannuation system for doctors in health centers will be organized. The whole question of the sale and purchase of public practices is to be discussed with the profession, particularly with a view to preventing the new public service from increasing the value of any individual practice.

Administration

Central responsibility to Parliament and the people will rest with the Minister of Health. Advising the Minister, but independent of him, there will be the Central Health Services Council, which will provide professional guidance on the technical aspects of health service. This would represent the main medical organizations, the hospitals, medical teaching, dentistry, pharmacy, nursing, midwifery and so forth.

In accordance with principles of decentralization and with present practice, county councils and county boroughs will be responsible for securing comprehensive and general health services within their areas.

But in order that the most efficient specialised services may be available for all areas, it will be necessary for certain areas to co-operate with each other.

Areas able to provide complete and self-contained hospital and specialist organisation will be designated by the Minister of Health after consultation with local bodies. County councils and county-borough councils in these areas will form joint authorities to administer hospital, consultant and allied services. Each joint authority will have the responsibility of planning the whole of the area's medical services, although actual provision and management of certain local services will be the responsibility of the individual county councils that form the Joint Authority. Alongside each new authority there will be a local health-services council — a professional and expert consultative body.

Local operation of child-welfare services will be the responsibility of the local authorities.

There will also be the Central Medical Board which, unlike the Central Health Services Council, will have executive functions in the working of the general practitioner service.

The Service in Scotland

The scope and purpose of the National Health Service will be the same in Scotland as in England and Wales. The above proposals will apply generally to both countries, subject to a few administrative differences.

Central responsibility will rest with the Secretary of State for Scotland. There will be a separate Central Health Services Council and a separate Central Medical Board for Scotland.

As local government organization and geographical features are different, the local administrative structure cannot be identical. About 80 per cent of the population of Scotland is concentrated in 17 per cent of the total area. Over wide areas there is a very sparse population, and local government units there lack the resources of urbanized England and Wales.

The five natural hospital regions of the country — based on Glasgow, Edinburgh, Aberdeen, Dundee and Inverness — are too large to serve as administrative units. It is proposed that each of these areas should have a regional hospitals advisory council with consultative and advisory functions. The actual administration of the hospital and consultant services would be entrusted to joint hospital boards, to be set up for smaller areas within the regions. (Thus the advisory and executive functions of the joint authorities in England and Wales would be divided in Scotland between two bodies.)

Clinics and other services not closely allied to the hospital service will remain in the hands of the major health authorities, who will be required to combine where necessary for the efficiency of the health service.

Health centers will be directly provided and administered by the Secretary of State for Scotland instead of by the local authorities, as in England. Instead of local health services councils there will be a local medical services committee for every joint board area. This will advise on the development of the general practitioner service and act as liaison between this and other parts of the National Health Service.

Finance

It is estimated that the total annual cost of the National Health Services will be about \$592,000,000, compared with about \$244,000,000 spent from public funds on the present health services.

The cost will be met both from central and local public funds. The extent to which these will be made up by contributions under a social insurance scheme remains to be considered in the forthcoming White Paper on social insurance.

The State itself will spend directly about \$134,000,000 on the new general practitioner service, including payments to chemists and the whole cost of health centers in Scotland. It will also give a grant of 50 per cent to help county and county-borough authorities to meet the increase in the total cost of the health services. The grant will be adjusted to give more help to poor areas and less to rich. Every new service other than the hospital and consultant service (health centers, dental and ophthalmic services and home nursing) will be assisted by 50 per cent grants. Joint authorities will receive a grant of \$400 a bed (\$140 in mental and infectious disease hospitals) in aid of hospital and consultant services. A similar grant will be paid to voluntary hospitals.

Conclusion

In conclusion it should be observed that the National Health Service will not only aim at the abolition of ill-health but at the positive improvement of good health. Its fundamental object is best expressed in the introduction to the White Paper, where it is stated that the Government wishes to ensure for every man, woman and child "that what they get shall be the best medical and other facilities available; that their getting these shall not depend on whether they can pay for them or on any other factor irrelevant to the real need — the real need being to bring the country's full resources to bear on reducing ill-health and promoting good health in all its citizens."

NOTE

The appointment of Dr. Alfred L. Johnson, professor of clinical dentistry, as administrative officer of the Harvard School of Dental Medicine and associate dean of Harvard Medical School, has recently been announced. The School of Dental Medicine on March 31 assumed responsibility for all dental education and research at Harvard University, succeeding the Harvard Dental School, the oldest university dental school in the United States, having been founded in 1867.

CORRESPONDENCE

A VISIT TO A TUBERCULOSIS SANATORIUM IN NORTHERN ICELAND

To the Editor: Five miles south of Akureyri, on the sharply rising land on the west side of the Eyjafjörður (Island Fiord), one can see the white walls of a three-story building of rather imposing size and pleasing appearance. A drive of easy grade from the main road soon brings one to the entrance of the large central building. The latter nestles against the hillside surrounded by smaller outlying structures, presenting the same white walls and clean-cut modern lines. This was the Kristnes Tuberculosis Sanatorium, which I had been eager to visit ever since I had first viewed it shortly after my arrival in the northern part of Iceland. No doctors I had known had visited it, so I was convinced that if I was to learn a little of how the Icelandic Government takes care of its citizens with tuberculosis, I should do well to visit one of their sanatoriums, of which Iceland has two. I had read that tuberculosis in Iceland has been for many years one of the chief causes of death among the adult population. Besides, I had heard many extravagant rumors about the disease, such as the one asserting that almost everybody on the island is supposed to have had it (at one time or another) and that one can catch it very easily. For more reasons than one I was eager to find out some facts for myself.

A week before my visit I had been instructed by an Icelandic friend of mine just how to ask for the physician in charge. Diligently I memorized the phrase, which phonetically sounded much like this: "Git yerkt tal lath with Rafnar Laeknir?" Translated it meant, "May I speak with Dr. Rafnar?"

With these few words on the tip of my tongue, I set out one afternoon for the sanatorium. In a short time I arrived at the small courtyard in front of the main building. From almost every window facing in my direction many people stared at me; these were the patients, and apparently the sight of a uniform was unusual for them. Considering their prolonged confinement, I realized later that their curiosity was only natural. A simple doorway led into a long corridor where patients were lounging; there was no vestibule or lobby. A young man stood just inside the door, apparently directing other visitors to the various parts of the hospital. In the phrase I had remembered, I asked him if I might speak to Rafnar Laeknir.* The wording and accent must have been fairly correct, as he quickly nodded and turned to

*It is the custom in Iceland for most physicians to be addressed by their first name followed by *Laeknir* — hence, Rafnar Laeknir.

guide me to a large two-story concrete house across the courtyard. Rafnar's apartment occupied the second floor. I knocked on his door and even called out his name, but all was silent and it was evident that the doctor was not at home.

Returning to the hospital, I found the man who had given me my first directions. He soon located the other resident physician, Richard Laeknr, who cordially greeted me. Fortunately he could speak English well enough for us to understand each other. He said he had plenty of time to talk and to show me whatever he could, so I felt reassured that I would after all learn something about the sanatorium in spite of the fact that I had not been able to locate Rafnar. It was not long before we were engaged in a lively conversation.

His office led off the long corridor, which I could now see was on the second floor. There were two rooms in the outer one were a doctor's office and a room containing for with German was a fairly

Richard Laeknr did much of the roentgenographic work of the hospital. His basic medical training had been obtained at the university in Reykjavik, which he attended for five and a half years. He then went to Denmark for instructions in obstetrics, as no course on that subject was finished and he received his doctor's degree. A year of internship followed in a Danish hospital, during which time he contracted pulmonary tuberculosis. Soon, however he was back at work as resident at a tuberculosis sanatorium near Jutland. After two years there he returned to Iceland. About six years ago he accepted his present position as the junior resident physician in this sanatorium.

At this point Richard Laeknr asked me if I cared to be shown about the hospital, and I was quick to assent. We first made the rounds of the rooms, which faced south as did the kitchen, dining room and the two large porches. The patients' beds were rarely more than two or three feet apart, no cubicles or screens between the beds were visible. The hospital was overcrowded, having twenty more patients than normally, the census was eighty. This overcrowding I later learned, was not limited to Kristnesi, at Vífilsstaður, the first tuberculosis sanatorium to be established in Iceland (1911), there were one hundred and eighty patients in a building planned for ninety. As Richard Laeknr and I were making our visit all the patients were resting quietly in bed for it was the early afternoon rest period. Richard Laeknr then told me that the buildings at Kristnesi had been erected in 1927.

We next stepped out on the two large porches, one reserved for men, the other for women. These were unoccupied at the time, but many steel beds were stacked up against the back walls, on the north side of the verandas. When the weather is pleasant and it is not too cold or windy, certain selected patients are permitted to use the beds. The latter are provided with mattresses and either sacks lined with sheepskin with the wool turned in, eiderdown comforters or woolen blankets (an important Icelandic product). This form of therapy is given more for the value of fresh air than for the exposure to direct sunlight, since most of the cases are of the pulmonary type.

Back in the main building on the first floor we passed through a spacious kitchen that appeared to be clean and well aired. Large windows on the south side admitted light to every part of the room. On the floor just above was a dining room in which a partition was being torn down. The sanatorium had just bought an excellent cinema projector equipped for sound, and more space was desired for the showing of American and British films. We next stopped in at one of the parlors, the eating utensils had been put away, a clean, orderly fashion, but Richard Laeknr demonstrated the large steam sterilizers in which they were placed, after being carefully washed. On the third floor we visited a small clinical laboratory where simple tests were carried out. Specimens of sputum (*kraki*) were examined on glass slides, using the Ziehl-Neelsen technic.

Returning to his office, we made ourselves comfortable in two of the straight backed chairs and continued our talk. I asked him if he would kindly give me more details regarding the treatment of his patients, he said he still had plenty of time to spend with me and would be only too glad to tell me all he could.

Patients are admitted to the two tuberculosis sanatoriums in two ways, one, directly from the patient's own physician, the other, through one of several state supervised tuberculosis stations, which are scattered throughout the island. On the patient's discharge from either of the sanatoriums, a brief summary of the clinical record is forwarded to the tuberculosis officer in Reykjavik, who is responsible for its incorporation in the public health records.

At Kristnesi any patient who has a fever must stay in bed at all times. No reclining chairs are used but patients may be propped up in bed with pillows if this makes them feel more comfortable. For those who are afebrile and whose disease is evidently nonprogressive, a graduated scale of exercise is arranged. At first, they are allowed up between noon and 1 p.m. for several days, if they continue to remain afebrile and symptomless the hours of being up are gradually increased over a period of weeks until the patients are up the whole day — 8 a.m. to 9 p.m. — with the exception of the rest periods during which they are supposed to sleep.

A patient's schedule for the day ran fairly close to this:

7 00 a.m.	At se
8 00 a.m.	Breakfast (Morgunmat)
10 30 a.m. to 11 30 a.m.	Rest period
12 00 noon	Dinner (Hádegismatur)
2 00 p.m. to 3 30 p.m.	Rest period
3 30 p.m.	Coffee, cocoa or milk with cakes and bread
5 30 p.m. to 6 30 p.m.	Rest period
7 00 p.m.	Supper (Aftandmat)
9 15 p.m.	Light out
8 00 p.m. to 10 00 p.m.	Cinema (usually held once a week)

The patient who continues to improve under this program may in time take short walks once to three times a day for periods of fifteen minutes increasing to one hour, if he tolerates outdoor weather. Pneumothorax treatments are given by either of the two resident physicians. This form of therapy is attempted in all the pulmonary cases and when it fails to produce the desired result, more complicated procedures are resorted to (pneumolyses, phrenicoplexes, rib resections and so forth). About six operations of this type are performed each year at the Akureyrri Hospital (*Sjúkrahús Akureyrri*) by its chief surgeon Gutmundur Karl Laeknr (Petursson), who at the time of my visit was attending a meeting of the American College of Surgeons in Philadelphia. Patients who for one reason or another are not able to receive this care are required to adopt longer rest periods and a more graduated treatment schedule.

Patients with evident tuberculous involvement of the pleura without demonstrable pulmonary infiltration of the lymph nodes or of the skin are encouraged to expose themselves to the direct rays of the sun or to sun lamps. Kristnesi has one of the mercury vapor type. Exposure is carefully regulated. Treatments at first are brief, later the exposure periods are increased to suit the toleration of the patient.

At night and during rest periods, the windows of the patients' rooms, which are large even by our standards, are kept open as widely as possible. Frequently however, they have to be kept closed owing to the high winds so common in this region. Drafts are sedulously avoided to minimize air-borne spread of the tubercle bacilli. The main building had ventilating conduits but as a result of a roof fire the previous year, these had had to be blocked up. It is realized that the present ventilating system is unsatisfactory, but funds for its improvement are lacking.

The patients are encouraged to keep their minds occupied with varied interests. Although no formal occupational therapy work is done at the sanatorium, ambulatory patients do a considerable amount of weaving on small light wooden frames that can be held in the lap, knitting and embroidery are popular with the women. The value of this type of therapy is being increasingly appreciated in the sanatoriums in Iceland, and plans have already been arranged at Kristnesi for the construction of a separate building for looms, drawing boards, woodworking benches and so forth. Richard Laeknr thinks that poor patients can do with their hands or feet is helpful for nonpsychotic depressive moods, in addition, he believes that the patient may develop more resistance while thus occupied that this work makes the time pass more quickly and finally that it is well to have those who are going home to more or less heavy household and farm work prepared to use their bodies, particularly their hands and feet.

The hospital stay varies from two months to ten years. Since almost all the patients are unable to pay the full cost

of their treatment, their expenses are partially or wholly defrayed by the Statc. Approximately 70 per cent of the patients admitted to Kristnesi or the other tuberculosis sanatorium are discharged healed or practically so. Richard *Laeknir* did not have figures available to show what the exact results were.

The sanatorium provides training for two student nurses at one time; each spends six months there as part of her nursing course, most of which is taken at the University Hospital (*Landspítalinn*) in Reykjavik. The latter, with 200 beds, is the largest general hospital in Iceland.

By now I had been almost two hours on my visit, but my host urged me to stop in at his apartment before going back to camp, and I agreed. It was just across the road down the west slope of the fiord — a one-story, white cement structure. As we entered through a small wooden gate, there were four or five young children scampering about the yard. We passed through a doorway into a narrow hall where toys and rubber overshoes were scattered about. There were two apartments, one occupied by Richard *Laeknir*, the other by the superintendent of the sanatorium. The former had just four rooms — a sitting room, bedroom, bathroom and kitchen — in which he, his wife and their one-year-old son, lived. The sitting room was small, yet comfortably furnished; mulberry-colored draperies framed the unusually large and pleasant windows; two striking oil paintings by Kjarval, Iceland's best-known contemporary artist, were tastefully hung on the wall opposite me; both depicted wide stretches of wild, forbidding, lava-strewn land. These paintings had been a gift in which Richard *Laeknir* evidently took pride. We sat down in two armchairs, near several brightly polished brass ornaments, including a huge, flat brass tray with small ash receptacles on it.

A few minutes after our arrival a buxom, smiling young woman entered the room and was introduced to me by Richard *Laeknir* as his wife. She spoke no English, but her cordial expression spoke for her and I knew right away that I was welcomed. She soon withdrew from the room, bowing slightly. From the sounds I shortly began to hear in the adjoining rooms, I knew she was preparing some refreshments. While she was gone, Richard *Laeknir* and I continued our conversation.

Up to 1930 Iceland had had high morbidity and mortality rates in tuberculosis. Both, fortunately, have dropped since then. The highest accurately recorded death rate from all forms of the disease was in 1920, when it was 210 per 100,000. In 1918 it had been 200. In 1929 and in 1932 it was still at this figure, dropping in 1937 to 130, and in 1941 to 80. At present the death rate is 100 per 100,000; since the population now totals 120,000, approximately 120 died last year from this disease.

Tuberculosis is being discovered and treated earlier than it was twenty years ago. Still, many cases are far advanced when the patients first arrive at the sanatoriums. This past year there seems to have been an increase in the incidence of the pulmonary type of the disease, chiefly in adolescents, particularly girls. The overcrowding in some of the larger cities, like Reykjavik, and the increase of measles this year are considered to be possible contributing factors. Also there still remain people who, though obviously ill, procrastinate about seeing a physician. As yet there is no law forcing one to go to a sanatorium unless the person has active (contagious) tuberculosis and lives in proximity to young children and adolescents. Chest roentgenograms are being increasingly utilized on the outside, even in the country districts; in some of the latter, especially where the local morbidity rate of tuberculosis is high, all except the very young have had them. Contacts are always skin-tested; usually the von Pirquet method is first employed; if this test proves positive, the Mantoux is used; if the latter is also positive and the patient is young, chest films are always taken. All patients at Kristnesi are skin-tested.

Tuberculosis in cattle is rare. Bovine-type bacilli are infrequently found, and there is little of the childhood form of the disease. Although most of the cows are not tuberculin-tested, the only milk that is rendered pathogen-free (stassinized — a Swedish method) is available solely in Reykjavik and Akureyri. A dairy farm outside Reykjavik supplies milk from a herd of tuberculin-tested cows for the use of young children.

All autopsies in Iceland are performed, with rare exceptions, by a specially appointed medical officer in Reykjavik. According to this plan, no postmortem examinations may

be carried out by either of the physicians at Kristnesi. An autopsy in a medicolegal case may be performed in any locality by a properly authorized physician. In the ordinary situation the majority of people, unfortunately, refuse to give their permission for an autopsy. When a patient dies at the Kristnesi sanatorium and permission has been obtained to perform an autopsy, the body has to be preserved in some manner, shipped to Reykjavik by boat, a voyage of two to three days, and finally be examined by someone unknown to the family. Under these conditions it is readily seen why not many permissions for autopsy are given. As yet no law exists that allows the performance of an autopsy without this permission.

Toward the conclusion of our talk, Richard *Laeknir* said a few words about two other diseases that in years past were frequent throughout this land — smallpox and leprosy. At present smallpox is nonexistent, chiefly owing, without doubt, to universal vaccination, which long ago was adopted in this country. All persons are vaccinated in their first year, in the fourteenth and at other times as deemed advisable in the individual case. Leprosy was common in the eighteenth century, when the disease, then rife throughout the world, spread to Iceland via (so it is thought) the Baltic States and Norway. Leprosariums were soon established: — the first at Laugarnes pronounced phonetically "Lerr-gar-ness"), just outside Reykjavik. (Laugarnes means "warm fountain near the peninsula"); the second at Kópavægur, about halfway between Reykjavik and Hafnarfjörður. At present there are about 20 cases of leprosy in Iceland.

Distribution of medical care was only sketchily discussed. In contrast to the present situation in the United States, it is largely under the direction of the Statc. Iceland is divided into fifty-two districts, with a physician assigned to each one. For assuming care of all indigents in his district, this man is paid a salary by the State, varying before the inflation (1941-1944) from 3000 to 4000 *kr.* (prior to 1941 a *krona* was worth 15 cents). The higher salary is obtained in the more sparsely populated districts. The physician is allowed to have private patients, but the latter are comparatively rare, so that his chief source of income is the salary paid him by the State. The position of being a district physician is now not much desired by the men just entering practice. Instead, the majority are eager to take up a specialty in Reykjavik. This poses a serious problem in the distribution of medical care in the near future. The threat of an actual oversupply of physicians in Iceland presents another problem, made more pressing with each passing year. The School of Medicine at the University of Reykjavik has been overcrowded for the past few years and, so far as Richard *Laeknir* knew, there has been no enforced limitation on the number of entering medical students; there has been solely the scholastic requirement to fill. The School of Medicine at present has a total of about sixty students, with about ten to each class. It was his opinion that three or four doctors each year would be sufficient for the needs of Iceland.

By that time his wife had returned with delicious coffee and several kinds of cakes and cookies and had set them out most attractively on a card table on the other side of the room. Richard *Laeknir* and I sat down on two small chairs so that we faced each other. I was surprised that his wife did not sit down with us and also partake of the refreshments, which I wish to repeat were delicious. Later I learned that it is the usual custom for the wife to wait on her husband when he is entertaining a stranger, and not to join in either the conversation or the refreshments.

My visit over, I took my leave, thanking them both as best I could for the truly delightful and interesting time I had had. My driver had just driven up to the outside gate in the ambulance, and soon I was well along the narrow road back to camp.

PAPILLOMATOSIS OF THE LARYNX IN CHILDHOOD*

A Report of Fifteen Cases

CHARLES F. FERGUSON, M.D.,† AND H. WILLIAM SCOTT, JR., M.D.‡

BOSTON

FIFTEEN patients with laryngeal papillomatosis were treated at the Children's Hospital in Boston during the ten-year period 1933-1942. It is the purpose of this paper to review briefly the clinical and pathologic aspects of the disease shown by these cases, with special reference to modes of treatment and results of therapy.

Papillomas are the commonest tumors of the larynx in childhood and should always be seriously considered by the physician in the differential diagnosis of chronic hoarseness. According to Jackson,¹ these tumors are the most frequent of all benign growths occurring in the larynx. In children,

The incidence of laryngeal papilloma as estimated from the literature is approximately 1 case per 1000 clinic patients. During the period covered by the 15 cases here reported, however, 82,644 children were examined in the Out-Patient Department of the hospital, an incidence of approximately 1:6000. Over 200 cases have been treated at Jackson's large bronchoscopic clinic in Philadelphia throughout his many years of service.¹ The disease is allegedly more frequent in males than in females, although in this series 10 patients were girls and only 5 were boys (Table 1). It may occur at any age, but its onset is most frequent between eighteen months and four

papillomas tend to be multiple and may arise from the vocal cords or the mucous membrane of any other part of the larynx, epiglottis or trachea. They are histologically benign, but, because of extreme rapidity of growth and an extraordinary tendency to local recurrence, coupled with the constant threat of glottic obstruction, their clinical nature is notoriously treacherous. According to Crowe and Breitsstein,² the mortality from laryngeal papilloma in children under five equals and possibly exceeds that of carcinoma of the larynx in adults.

years. According to Gerhardt,³ about one fifth of all cases are congenital. Only one child in the present series had symptoms dating from birth. In no case was there any familial incidence of the disease.

No conclusions can as yet be drawn concerning the specific etiology of papilloma of the larynx. It has frequently been suggested that a close relation exists between the common cutaneous wart and the histologically similar laryngeal papilloma. Ullmann⁴ in 1923 was apparently able to transplant the growths by means of a filterable agent, both to the skin and to the mucous membranes. The mucosal transplants developed after two or three months of incubation and were identical with the donor papillomas, both grossly and histologically. On the skin, the trans-

plants developed as flat warts, resembling microscopically and grossly the common verruca plana. Ullmann's series was small and poorly controlled, and his work has not been confirmed; nevertheless, it is extremely interesting. That a filterable virus is responsible for this disease is still a possibility.

Chronic laryngeal irritation from recurrent infection, dust and gases was formerly thought to play an etiologic role, but there is no evidence that it is of any

well defined. Varying stages of nuclear degeneration are seen throughout the horny layer.

According to Lipschutz,⁶ inclusion bodies are sometimes found in the epithelial cells of laryngeal papillomas. He describes these as basophilic and intranuclear. A search for inclusions was made in the pathologic material from the Children's Hospital cases, but none were found. The presence of nuclear inclusions presumably adds support to the virus

FIGURE 1. Photomicrograph Showing a Cross Section of the Processes of a Papilloma.

true significance. It is interesting that Jackson¹ saw over 25 cases of adult papilloma in veterans of World War I who had been gassed.

Histopathologically, laryngeal papillomas are distinctly benign neoplasms, with little to suggest a chronic inflammatory process. They consist of pedunculated or sessile processes of proliferated squamous epithelium with a central core of connective tissue and small vessels. They are frequently branched, and peglike projections of epithelium may be seen extending down into the underlying stroma. The cells are well-differentiated, mature epithelial cells, and there is no true invasion of the stroma or extension into the submucosa below the intact, well-defined basement membrane (Figs. 1 and 2).

The cells lining the basement membrane are identical with those of the basal layer of normal laryngeal mucosa and of normal epidermis. They tend to be elongate, with hyperchromatic nuclei. Mitotic figures are extremely rare. Farther out from this basal layer there is a transition to larger, polyhedral cells with clear, vesicular nuclei containing one or more nucleoli. Keratinization of this outer layer is usually

theory of etiology of laryngeal papilloma. Considerable difficulty, however, is encountered in differentiating basophilic intranuclear inclusion bodies and the various forms of nuclear degeneration so frequently seen in the horny layers of a laryngeal papilloma.

The gross appearance of these tumors is characteristic. On laryngoscopic examination they are seen as glistening, grayish-pink or yellowish-pink, mulberry-like masses with a punctate or finely nodular surface that project from the mucosa of the cords, anterior commissure or elsewhere. They vary in size from nodules only a few millimeters in diameter to fungating masses as large as an olive (Fig. 3). There is practically never the appearance of infiltration of the underlying structures or ulceration of the cords, as in carcinoma. Although implantations may occur and local recurrence is the rule, these tumors are always benign, never invading or metastasizing.

In children, the lesions are usually multiple, as opposed to the more frequently single adult form. The vocal cords are the most frequent sites, but the tumors may occur anywhere in the larynx. Often the

anterior commissure is a favorite region of extremely prolific growth. Extension or implantation on the mucosa of the epiglottis, subglottic region or trachea is common, and the lesions have been known to appear in the fauces or buccal cavity and even to

may occur. Stridor and dyspnea develop as the tumors mechanically obstruct the glottic airway.

Laryngeal dyspnea was a fairly late development in these cases, occurring as a rule only after untreated hoarseness had been present for several months.

FIGURE 2. Photomicrograph Showing Well-Differentiated Cells and a Well-Defined Basement Membrane.

involve the lips. In this series, palatal and tonsillar implants were discovered and removed.

The symptoms produced by papillomas are in no way different from those of any laryngeal tumor, namely, hoarseness, aphonia, stridulous breathing,

FIGURE 3. Photograph of a Laryngeal Papilloma.

dyspnea and, later on, the resultant signs of increasing laryngeal obstruction. Of these, progressive hoarseness is the most frequent presenting complaint, but exists only when the tumor interferes with the vibration, approximation or tension of the vocal cords. Loss of voice to the point of complete aphonia

There are notable exceptions, however, when laryngeal obstruction develops early and acutely, as a polypoid tumor mass is prolapsed or sucked into the glottis, necessitating emergency tracheotomy. This occurred in a patient who had been given ether anesthesia preparatory to direct laryngoscopy, and an emergency tracheotomy had to be done. Laryngoscopy revealed a pedunculated, olive-sized mass that had prolapsed into the glottis and was firmly impacted between the two cords. In retrospect, it was probably unwise to have given this patient a general anesthetic, even though she had manifested only the mildest signs of laryngeal obstruction. Our policy has since been to use no anesthesia when even the slightest suggestion of respiratory difficulty is present. Cough is occasionally present, but was a minor symptom in these cases. When a large mass of tumor projects upward from the larynx, dysphagia may occur.

The diagnosis of papilloma of the larynx can be made only by laryngeal examination, and in children direct laryngoscopy is almost always necessary to accomplish this. Lateral roentgenograms of the neck, especially laminagraphs, are occasionally helpful. Biopsy should be performed in all cases, although this procedure is much more important in adults than in children, since in the latter carcinoma of the larynx

is so rare as to be practically unheard of and the clinical appearance of the papilloma is most characteristic. The physician who is confronted with the problem of progressive hoarseness in an infant or child must consider many diseases in differential diagnosis. The most frequent of these are papilloma or some other benign tumor, a foreign body, chronic laryngitis associated with sinusitis, syphilis or tuberculosis, so-called "screamers' nodes," laryngotracheitis, malformations, congenital webs, recurrent paralyses, hypertrophic ventricular bands and so-called "laryngomalacia." No definite diagnosis can be conclusively made without direct laryngoscopy, and the importance of carrying out this procedure without delay cannot be overemphasized.

Papillomas of the larynx in childhood are always benign, and the disease is almost always self-limited. These two basic premises dictate that treatment be as conservative as possible. If the delicate structure of the larynx is preserved intact with no operative or irradiational injury to normal tissue, the papillomas eventually cease to recur and the child regains a normal larynx and a normal voice. As a rule, after removal the tumors recur with great persistence, but they usually disappear spontaneously after a few years, regardless of treatment. There seems to be an activity phase of these growths during which repullulation occurs consistently until the process is "burned out." This has been called by Broyles⁶ the "juvenile phase." Following this, the tumors may persist indefinitely without treatment, but excision at such a time usually results in a permanent cure. In this phase of relative inactivity papillomatosis in children resembles the adult form of the disease, which can usually be permanently cured by a single excision.

The average duration of the disease in the present series was three years. Three patients are still under treatment, and 2 of these have had symptoms for five and eight years, respectively. The briefest course of the disease was in a boy of three years of age who had had symptoms for eight months and was cured by a single endolaryngeal excision. Remarkable cases are reported in the literature in which the disease persisted for twenty or thirty years. In Lejeune's⁷ case, the papilloma persisted for twenty-one years, despite all forms of treatment, including ninety-seven operative procedures, finally terminating fatally with the development of squamous carcinoma of the larynx.

The variety of therapeutic measures advocated by different authors in the treatment of laryngeal papilloma is strong evidence of the uniform lack of consistent success of any single mode of therapy now available. Various medicinal measures have been advised. Most of these consist of the local application of absolute alcohol, zinc chloride, silver nitrate, iodine, salicylates, acid nitrate of mercury, nitric acid or other escharotics. *Thuja occidentalis*, potassium iodide and particularly calcined magnesia have been used systemically. In the judgment of writers,

none of these medicinals have any effect on the course of the disease. We have had no experience with them.

Broyles⁶ at the Johns Hopkins Hospital has recently reported 5 cases treated locally with an estrogenic hormone preparation (Amniotin). The rationale of this therapy was based on the well-known tendency of laryngeal papillomas in children to disappear spontaneously at, or just before, puberty, and on the fact that local applications of estrogenic hormones to the vaginal mucosa of prepubescent girls produce a change from the childhood to the adult type of epithelium. Such changes in the laryngeal mucosa, however, have not been demonstrated, although alterations in the voice at puberty in both sexes are self-evident. The results in Broyles's series were not convincing, in that in each case the disease had existed for many months before the beginning of treatment and an apparent cure was obtained only after the continued use of estrogens for four to eight months; in other words, success was attained at about the usual period in the course of the disease when spontaneous remission might be expected. One of our patients was given a course of local estrogen therapy, Amniotin in oil in 1-cc. (10,000-unit) doses being applied to the papillomas and adjacent laryngeal mucosa once weekly for seven months, with no detectable change in the rate or character of the growths, grossly or histologically. In our opinion, the efficacy of this method of treatment, applied in such a small number of cases, is as yet unproved.

Radical operative procedures, such as laryngofissure or thyrotomy, were formerly used in treatment of papilloma of the larynx. These methods are to be wholeheartedly condemned in view of the benign nature of the disease and the laryngeal stenosis and permanent laryngeal damage that usually develop in children following the use of these radical surgical methods.

Mackenzie⁸ in 1901 first advocated the use of tracheotomy and expectant treatment in cases of papilloma. The rationale was to provide an adequate airway and to keep the larynx at rest until the tumors spontaneously disappeared. Clark⁹ in Boston in 1905 reported 14 cases treated in this manner, and pointed out that if the tumors persist after the age of puberty in a tracheotomized patient, endolaryngeal excision is most apt to result in success, since the tumors have then usually passed out of the phase of activity. In our opinion, tracheotomy is not necessary unless signs of laryngeal obstruction persist, or unless the patient cannot be kept under relatively close observation. The care of a tracheotomized child at home is always a problem, and it often proves difficult for the mother to manage the changing of tubes, maintain adequate cleanliness and exercise constant supervision. One of our patients died of asphyxia at home as a result of his removal of the tube without the mother's knowledge.

Irradiation of the growths by x-ray or radium has had considerable success in the hands of several authors. New,¹⁰ of the Mayo Clinic, advocated the use of radium endolaryngeally and externally. This method was also supported by Crowe² at the Johns Hopkins Hospital. Foster¹¹ in 1933 reported 3 cases treated with x-rays. Although in some cases radiation therapy apparently results in cure of papillomas, the danger of irreparable damage to the delicate laryngeal cartilages is great enough to condemn this method of treating benign, self-limited tumors. Necrosis may easily be produced in the highly sensitive, growing cartilages of the larynx in children. It is also possible that external irradiation of the larynx will have some untoward effect on the thyroid gland of a growing child. Jackson¹² reports that he has never seen a cure of papilloma of the larynx that could be attributed to x-ray therapy.

Fulguration of the growths by the endolaryngeal application of diathermy or cautery has been frequently used in some clinics, but the resulting damage to the cords and laryngeal cartilages makes its use unwarranted. Moreover, as Jackson¹ points out, recurring papillomas of the larynx constitute a repullulation from the surface epithelium, and nothing is to be gained by cauterization of the base of each tumor. Another independent lesion often develops elsewhere along the mucosal surface.

At the Children's Hospital, the method of choice in treatment of laryngeal papillomas is that of repeated endolaryngeal excision. This is accomplished in most cases by direct laryngoscopy under general anesthesia with Avertin (80 to 100 mg. per kilogram of body weight), supplemented by ether. The tumors are gently removed with biting forceps repeatedly applied. A twisting motion of the wrist cuts off the tumors flush with the adjacent mucosal surface and leaves the basement membrane of the underlying mucosa intact. No resistance is usually encountered unless one has made the error of grasping normal tissue. The anterior-commissure laryngoscope is also employed to gain free access to the subglottic region as well as the anterior commissure. Suspension laryngoscopy is neither necessary nor advisable.

Tracheotomy is done at this hospital only when dyspnea or signs of laryngeal obstruction exist, being otherwise avoided. It was employed in 9 of the 15 patients in this series, but in none of the more recent ones. An effort is made to examine the patients under treatment every two to four weeks, and excisions are carried out as often as recurrence demands. This method of repeated excision is not suggested as a specific means of cure, since in practically all cases these growths tend to recur; but when it is performed at sufficiently frequent intervals, an excellent airway is constantly maintained, without the necessity and added risk of a temporary tracheotomy. In 6 cases, only a few

excisions at intervals of three to six months were necessary for permanent cure. In 3 others, a single excision sufficed. In the remaining 6 cases, however, excisions were necessary as often as every two to four weeks, with an occasional respite of one to two months, the periods of therapy averaging two years. A patient who is still under treatment has had thirty-five excisions during the course of five years.

Three patients received brief courses of x-ray therapy in addition to endolaryngeal excision. In no case was any improvement obtained, and in 1 case actual stimulation of growth seemed to result. As mentioned above, 1 case was treated with local estrogenic hormone after the method of Broyles,⁸ with no change in the rate or character of the growths after six to seven months of weekly applications. Multiple excisions have since been necessary.

Three patients died while under treatment, but only one of these deaths can be directly attributed to the papilloma. This fatality occurred in a child who died suddenly of asphyxia at home shortly before the appointed time for a readmission for excision. Death apparently resulted from prolapse of a mass of papilloma into the glottis, causing sudden strangulation. In the second case, mentioned above, death resulted from asphyxia when a two-year-old baby pulled out his tracheotomy tube at home. The third patient died at another hospital of laryngeal diphtheria.

Three patients are still under treatment, and a fourth, who was under treatment for over six years, having undergone thirty-eight endolaryngeal excisions, was recently found to have recurrent papilloma. This patient, now seventeen years old, was recently called back for examination five years after the last excision. A laryngoscopy and bronchoscopy performed three months after the last excision had been negative, and the patient had been discharged because he had reached the hospital's age limit of twelve years. He had been asymptomatic and had consequently not bothered with follow-up examinations in an adult clinic, to which his case had been referred at discharge. Excision of the papillomas at the present time will probably result in permanent cure, since the phase of activity has most likely passed.

Eight cases were cured by endolaryngeal excision. In each of these the voice and larynx are normal and no complications resulting from treatment exist. No recurrences have occurred in follow-ups ranging from one and a half to six years.

SUMMARY

Fifteen cases of papilloma of the larynx in childhood are reported.

Papillomas are the commonest tumors of the larynx in childhood, and are benign, self-limited growths that tend to recur but also to disappear at puberty.

The etiology of the disease is unknown.

The diagnosis should be suspected in any case of progressive hoarseness in a child, and direct laryngoscopy should always be performed.

The recommended treatment is repeated, careful superficial excision, with tracheotomy reserved for those cases with severe laryngeal obstruction or for cases that cannot be kept under frequent observation. Radical surgical methods are condemned. Radium or x-ray therapy is not without danger.

Of the 15 reported cases, 8 show excellent clinical cures, each patient having a normal voice and a normal larynx. Three patients are still under treatment, and only 1, who was discharged as normal five years ago and is now seventeen years of age, has had a recurrence. Three patients died, 2 as a result of asphyxia at home and 1 of laryngeal

diphtheria. Only 1 of these deaths was directly attributable to the papilloma.

CAUSALGIA AND GANGRENE: RARE COMPLICATIONS IN MENINGOCOCCAL MENINGITIS*

Report of a Case

COMMANDER PHINEAS BERNSTEIN (MC), U.S.N.R.†

NEWPORT, RHODE ISLAND

IN the enormous recent literature dealing with meningococcal meningitis, no reference to skin and toe gangrene terminating in spontaneous amputation nor to the more unusual syndrome of causalgia has been observed. In the case reported below, these conditions became manifest after the initial fulminating attack subsided, and caused protraction of disability for four months. That there was a common etiologic basis for these pathologic changes is uncertain and difficult to maintain. Their rarity in this disease, the uncontrollable and intractable pain, the extended period of illness and the ultimate loss of body members are sufficiently noteworthy to warrant a brief report.

REPORT OF CASE

M. H., a 34-year-old woman, was admitted to the Newport Hospital, on January 31, 1943. She had been up and about with a "head cold" for a few days, until chills, severe pains in the extremities and back, and moderate fever set in. On the sudden appearance of diffuse purpuric skin lesions and a stiff neck, she was admitted to the hospital.

Between 1929 and 1937 the appendix, internal genitalia and gall bladder were removed and a nephrotomy for kidney abscess was performed. In 1939, the patient had a "nervous breakdown." Except for an underlying anxiety psychosis, there were no illnesses except those treated surgically. The menopause was operatively induced in 1935;

prior to that time, the menses were normal. There had been no pregnancy.

Physical examination showed a confused, transiently irrational patient who repeatedly demanded relief from a cruciating pain in the head, trunk muscles and extremities. The skin was cold and clammy, and the limbs were severely painful, stiff, cold and numb. There was marked spasm of the neck and back muscles, and the knee, ankle, wrist and elbow reflexes were hyperactive. The Babinski sign was equivocal. No lid ptosis, squint, nystagmus, facial paralysis or optic neuritis was found. There was no incontinence. The head and neck revealed no other abnormalities except injection and reddening of the pharynx, uvula and tonsillar tissue. The heart and lungs were normal. Except for a well healed suprapubic scar and skin hyperesthesia, the abdomen revealed no unusual signs. A pelvic examination was not performed.

The skin contained numerous huge, irregular, moderately indurated purpuric areas, among which were petechial hemorrhages ranging from those of minute size to coalescent groups or patches 2 to 5 cm. in diameter. Except for the face and hands, these were scattered over all parts of the body—especially on the thighs, neck and extremities. On the dorsum of each foot was an area of purpura involving the central toe and a space 2 cm. proximal to them; this was well demarcated and leathery and so painful that contact with bed sheets was unbearable.

The temperature was 99°F., the pulse 100, and the respirations 20. The blood pressure was 110/60. The white-cell count was 19,600, with 84 per cent polymorphonuclear leukocytes and 16 per cent lymphocytes. The red-cell count was 5,000,000, the hemoglobin 90 per cent, and the color index 0.8. The urine was normal, and a Kahn test was negative.

Spinal puncture yielded 25 cc. of thick yellow fluid under increased pressure. The white-cell count of the fluid was 670, the globulin level + + + +, and the sugar level slightly below normal. A direct smear revealed many gram-negative biscuit-shaped extracellular diplococci. A spinal tap on the following day revealed a white-cell count of 5100, and the direct smear showed the same findings as the previous one.

On the 2nd hospital day, a deep cyanosis of the mucous membranes appeared after 90 gr. of sulfadiazine had been

given. The sulfadiazine level in the blood was 3.9 mg. per 100 cc. Halving the daily dosage of sulfadiazine during the next three days reduced the blood level to a negligible quantity. At no time was there leukopenia or secondary anemia. During the first 10 days of the disease the excruciating pain, generalized purpuric eruptions and disturbances of the sensorium dominated the clinical picture. Satisfactory relief was unobtainable with large doses of opiates, and at no time was there complete freedom from pain. Vitamin B₁, glucose and physiologic saline solution were administered intravenously daily to supplement the limited diet.

On the 6th day, the patient complained of a lump in the throat, dysphagia and pharyngeal soreness. There was no choking sensation. Examination failed to reveal a cause for these complaints. By that time the painful, indurated purpura of the toes had become gangrenous and well demarcated, and there, as in several larger areas of ecchymosis on the trunk, thighs and legs, a generalized sloughing began. Daily debridement maintained free drainage, and after this the hitherto elevated temperature (102 to 104°F.) subsided and remained normal. Caudal anesthesia induced by a mixture of 30 cc. of 1 per cent novocain and 70 cc. of physiologic saline solution did not relieve the severe pain in the feet. This pain, in fact, did not completely disappear until the 75th day, when the gangrenous members — the 2nd, 3rd, and 4th toes of the right foot and the 2nd and 3rd toes of the left foot — were surgically disarticulated at the metatarsophalangeal joints. At that time, the lesions of the thighs, trunk and legs had entirely healed and large, indurated, reddish-brown scars had replaced the sloughed purpuric areas of skin. Heat-cradle therapy, whirlpool baths and massage were employed for restitution of function of the lower extremities.

Throughout the hospital stay, the disturbances described above were continuously complicated and enhanced by a painful lesion in the right arm and hand, which followed a causalgia pattern. During the first week, cyanosis, numbness and coldness were followed by hyperesthesia, tingling and hot sensations and an incessant throbbing pain. The extremity became edematous, and the moderately cyanotic skin assumed a glassy and translucent appearance and a putty shade. The fingers and hand became puffy, and continued to tingle with an intermittent burning pain superimposed on a constant sensation of aching soreness. The slightest vibration or motion aggravated the pain. Two palmar blocks with 20 cc. of 1 per cent novocain, analgesics, somnifacients and opiates in huge doses failed to furnish any relief. There was never any evidence of abnormal vascular pulsations or thrombosis.

The constant suffering, insomnia and mental anguish of the patient caused by the pain in the right arm were reflected in her debilitated and cachectic appearance. The excruciating pain seemed at all times out of proportion to the visible changes in the extremity. It confined itself solely to the course of the ulnar nerve, descending from the medial aspect of the arm, where it remained for 36 days, into the area above the styloid process of the ulna bone, where it persisted for 40 days, and thence into the palm and the 4th and 5th fingers. On the 100th day, the pain disappeared.

Long immobilization caused atrophy of disuse, cyanosis, edema and hirsutism and markedly altered the appearance of the involved limb. That profound trophic changes had taken place was indicated by an x-ray film taken prior to discharge on the 120th day. General osteoporosis, particularly in the extremities of the bones rather than the shafts, was observed, and there was also new destruction of the cortex and cartilage.

DISCUSSION

Gangrene of the toes and also lesions involving large areas of the skin are rare complications of meningococcal cerebromeningitis. In the present case, their coincident appearance and the simultaneous necrosis, sloughing and healing indicate a

common etiologic factor. No stained slides demonstrating meningococci, however, were made from either the skin or toe lesions. The cause was probably a trophic disturbance based on a common, widespread vascular lesion, produced by a peripheral thrombosis — embolic or autochthonous — or by a peripheral vasospasm from an exotoxin.

The pain associated with the gangrene was probably due to peripheral neuritis, secondary to nutritional changes in the surrounding tissues affected by vascular lesions, and the intensity of pain varied proportionately with the degree of necrobiosis, disappearing finally after complete disarticulation. Pain accompanying gangrene is not uncommon.

The syndrome in the right arm may properly be attributed to causalgia, a rare and bizarre clinical picture of pain without visible lesions, thought to be due to vascular, neurogenic or psychic phenomena. The presence of all the latter phenomena and the absence of demonstrable primary tissue changes satisfactorily explain the intense and constant pain in the right arm and hand. Had the pain been due to a vascular lesion alone, its prolonged duration and marked severity would have been accompanied by tissue changes more profound than actually existed. Had it been occasioned by hysteria or psychoneurosis alone — and these were undeniably present — it would be difficult to explain the moderate tissue changes as well as the selective reference of pain, completely and at all times, to the course of the ulnar nerve. That the cause was a neuritis due to a vascular disturbance — toxic, embolic or thrombotic — in the nutrient vessel of the nerve itself seems to be the most satisfactory explanation even though it is extremely difficult to prove. Thus the paradox of severe pain in the arm and hand associated with only minor pathologic changes, and the uncertainty whether the etiologic factor was neurogenic, vascular or psychic, warrant a diagnosis of causalgia.

SUMMARY

A case of cerebrospinal meningococcal meningitis is recorded because of two rare complications, purpuric dry gangrene of the toes and of scattered areas of the skin and causalgia of the right upper extremity. The important aspects of these complications were the prolonged duration of the disease, the loss of body structures because of necrosis and the uncontrollable pain. The emboli that probably caused these phenomena were of profound clinical significance because of the possibility of their fortuitous destination in vital areas of the body — brain, heart and lungs. The prognosis was therefore guarded.

CLINICAL NOTE

VOMITING OF AN OPEN SAFETY PIN¹

EDWARD B. BENEDICT, M.D.†

BOSTON

THE successful vomiting of an open safety pin is such a rare occurrence that the reporting of such a case seems justifiable. Only 3 similar cases have been found in the literature. In 1909, Good-

FIGURE 1. Roentgenogram Showing the Safety Pin in the Stomach.

man¹ reported a case in which an open brooch 6 cm. long was swallowed by an eight-month-old baby and vomited fifteen weeks later. In 1916, Earp² reported the case of an eight-month-old baby who vomited an open safety pin 5 cm. in length. In both these cases, however, there was no x-ray or other proof that the safety pin ever reached the stomach, and the size of the pin as compared with the size of

*From the Massachusetts General Hospital

†Instructor in surgery, Harvard Medical School, associate visiting surgeon, Massachusetts General Hospital

the child makes these accounts seem doubtful. In 1927, Orton³ reported the spontaneous expulsion of an open safety pin from the stomach by a seven-month-old baby, who expelled it into the esophagus within one week after swallowing it (confirmed by x-ray examination, and as arrangements were being made for an esophagoscopy regurgitated it from the esophagus into his mother's hand. The size of the pin was not recorded.

REPORT OF CASE

R. S. (M.G.H. U-381630), a 3-year-old girl, entered the Emergency Ward of the Massachusetts General Hospital on November 9, 1943, having swallowed an open safety pin a few minutes before entry.

Physical examination showed a child in no distress, with no abdominal tenderness and normal temperature, pulse and respirations.

X-ray examination (Fig. 1) revealed a medium-sized open safety pin in the stomach, with the point slightly bent toward the keeper. I advised keeping the patient in the hospital a day or two, expecting that the pin would be passed through

FIGURE 2. Photograph of the Safety Pin.

the intestinal tract without difficulty. A few hours later however, the patient vomited and the pin was recovered (Fig. 2). It measured 2.7 cm. in length.

Except for an attack of vomiting (without hematemesis) the day after the expulsion, the patient had no further symptoms.

The whole episode took place within a 5-hour period. The fact that the point was bent toward the keeper must have facilitated the swallowing and subsequent vomiting.

Correction: In the paper "Meningitis in Children," by Drs. Charles H. Hollis and James Marvin Baty, which appeared in the March 9 issue of the *Journal*, the figure "15,000" in column 1, line 52, on page 280 should be "1500."

MEDICAL PROGRESS

INHALATION THERAPY (Concluded)*

MAURICE S. SEGAL, M.D.†

POSITIVE-PRESSURE THERAPY

The use of positive-pressure therapy, as a rule employing a mixture of oxygen and helium, has not become so widespread as it should be. It is indicated in the treatment of various types of pulmonary edema, bronchial asthma and obstructive respiratory disease.

Physiological Basis and Clinical Application

Barach and his associates¹³¹⁻¹³⁵ established the clinical application and usefulness of positive pressure and the physiologic factors involved in the treatment of obstructive dyspnea and acute pulmonary edema. They devised two types of apparatus, of which one provided positive pressure during both phases of the respiratory cycle,^{9,10} and the other provided it during expiration alone.¹⁶ The signs of pulmonary edema rapidly disappeared, and remained absent so long as the pressure was applied or until the original cause was removed. The application of a gentle internal distending force served to keep the bronchioles patent and opposed the hydrostatic pressure within the capillaries. Barach compared this process with that of putting a finger on the capillary wall itself. He demonstrated by its use a reduction of the negative intrapleural pressure and frequently a lowering of the total pulmonary ventilation. Other modifications in circulatory function were reported, such as an increase in venous pressure that maintains the return of blood to the right side of the heart and a prolongation of circulation time, especially marked in congestive failure. These modifications tended to prevent overfilling of the heart and acted similarly to the application of a tourniquet to the extremities. There was also x-ray evidence of narrowing of the transverse cardiac diameter by the application of high mask pressures.

Positive pressure can be effectively administered through the Barach-Eckman-Molomut mask, which is metered for positive pressures up to 4 cm. of water in the expiratory phase only, or in the hood apparatus during both inspiration and expiration. The patient can be kept in the hood or mask with proper humidification for as many days as necessary. When the need for positive pressure no longer exists, the mask can be used without employing the metered disk for positive pressure and the desired percentages

of oxygen can be given, or the patient may be transferred to a tent if this is considered more desirable. The percentages of oxygen may be gradually lowered before the complete cessation of treatment in order to prevent the recurrence of anoxia. Cerebral and cardiorespiratory symptoms may follow the sudden stopping of oxygen therapy in cases of chronic anoxia.

Generally, positive pressures of 2 to 6 cm. of water are sufficient for preventing or treating pulmonary edema. Pressures above 6 cm. may diminish the return flow of blood to the right side of the heart. In some cases higher pressures may be found necessary for short periods. Theoretically, shock may be considered a contraindication to the use of positive pressure. No difficulty need be encountered, however, if low pressures are used, beginning with a pressure of 2 cm. of water and cautiously increasing it as needed.

Anesthesia for Thoracic Surgery

There are essentially no dangers associated with the proper use of positive-pressure therapy of 2 to 6 cm. of water as described above. Anesthetists and thoracic surgeons have employed positive-pressure anesthesia with an intratracheal catheter or closed face mask. The maintenance of sufficient lung function and controlled respiration during a surgical pneumothorax may be obtained by the use of proper mixtures of anesthetic agents under sufficient pressure. The accompanying hazards and disadvantages have been described by Bradshaw,¹⁴⁶ Heidrick et al.,¹⁴⁷ Marcotte et al.¹⁴⁸ and others. Bradshaw reported a case of mediastinal emphysema, and Adams¹⁴⁹ and Heidrick et al.¹⁴⁷ several cases of emphysema. Adams¹⁴⁹ described a case of mediastinal emphysema and subcutaneous emphysema of the neck and face following an asthmatic attack with severe coughing. He stressed the importance of properly controlled low positive pressures and discussed his experimental data, concluding that intrabronchial pressures of 52 to 58 mm. of mercury were necessary to produce a rupture of the visceral pleura. Much lower pressures were needed to produce a rupture of the alveolar walls. These experiments substantiated the previous reports by Coryllos¹⁵⁰ and Macklin,¹⁵¹ and should stimulate interest in the dangers of manipulating the anesthesia bag too vigorously or too often. Adams¹⁴⁹ stated that the intrabronchial pressure may rise as high as 25 to 30 mm. of mercury with a single squeeze of the

*From the First and Third Medical Services, Boston City Hospital, and the Department of Medicine, Tufts College Medical School.

†Assistant professor of medicine, Tufts College Medical School, outpatient physician, Boston City Hospital, junior visiting physician, Beth Israel Hospital.

bag. This corresponded to Barach's⁷⁸ demonstration in a tracheotomized patient that a forceful grunt developed a pressure as high as 30 cm. of water. These disadvantages were overcome by Crafoord.¹⁵² He described a new continuously flowing gas-anesthesia machine provided with means for mechanically controlled, automatized respiration. He reported no injuries to the lungs in a large series in which pressures up to 20 cm. of water were employed. These pressures were considerably higher than those commonly employed for the management of pulmonary edema or bronchial asthma in man.

Obstructive and Asthmatic Dyspnea

Barach^{108, 153, 154} summarized the sequence of events that follows resistance of obstruction to inspiration. There is at first a rapid and progressive increase in the intrapleural negative pressure in order to pull sufficient air into the lung. The resistance of the pulmonary bed is lessened and there is at first an increase in the pulmonary blood flow. As the intrathoracic negative pressure mounts, blood continues to enter the lungs through the right ventricle, but the passage of blood through the lungs into the left auricle and from the left ventricle into the extrathoracic aorta is hindered by the high negative pressure within the chest. A progressive accumulation of blood in the lung follows, with a consequent increase in capillary blood pressure. The physical effect of a pathologically elevated negative pressure within the chest is to exert a direct suction action on the pulmonary capillaries, thus tending to cause exudation of serum. The progressive increase in congestion and edema of the lungs requires increased effort for pulmonary ventilation, which in turn manifests itself as an increase in intrapleural negative pressure with the production of additional congestion and edema. The diffusion of oxygen through the swollen pulmonary membrane is diminished. Irregular ventilation through partially obstructed bronchioles increases the anoxia. The rapid, shallow breathing of itself promotes anoxemia, and progressive oxygen want becomes an additional factor as a stimulant to respiration and as a cause of final respiratory failure. The production of pulmonary edema is furthered by anoxemia, which has been shown by Landis¹⁵⁵ to increase capillary permeability.

Barach, Martin and Eckman^{142, 143} demonstrated, both clinically and experimentally, lowering of the intrapleural negative pressure in the lungs by the breathing of therapeutic gases under positive pressure. When the lung was expanded by positive pressure from the atmosphere, a reduced suction pressure was required during inspiration. Helium with oxygen decreased the effort necessary for pulmonary ventilation, thus lowering the negative intrapleural pressure. Macklin¹⁵⁶ demonstrated that normally in addition to the inspiratory elongation

of the bronchial tree, the bronchioles and smaller bronchi dilate during inspiration and constrict during expiration. Barach first observed that a severe asthmatic patient was benefited by pursing his lips during expiration. This led to Barach and Swenson's¹⁴⁴ work. They used lipiodol and conclusively demonstrated a relative increase in the diameters of the small bronchi during the expiratory cycle under positive pressure, which were 25 per cent more open with positive pressure. The positive pressure acted as an internal distending force tending to diminish the constriction of the bronchioles during expiration.

In asthmatic dyspnea the expiratory phase is prolonged owing to bronchial constriction. In obstructive dyspnea the intrapleural negative pressure is increased during inspiration. When air or oxygen mixtures are breathed under positive pressures, the abnormally elevated negative intrapleural pressure is diminished and the dyspnea is alleviated. Barach⁷⁸ pointed out that Nature provides a helpful internal mechanism in the expiratory grunt of the patient with lobar pneumonia and in the pursed lips of the asthmatic patient during expiration. The expiratory grunt maintains a more patent airway and opposes pulmonary edema.

Pulmonary Edema of Varied Etiology

Barach⁷⁸ in a recent paper once again demonstrated, in 5 patients critically ill with pneumonia, the value of properly directed positive-pressure inhalation therapy. He concluded that positive pressure is useful in the treatment of pulmonary edema due to increased hydrostatic pressure and anoxia, as seen in heart failure, or to changes in permeability of the pulmonary capillaries, as seen in pneumonia or gas poisoning. Barach offers a lucid explanation for the mechanism of pulmonary edema occasionally observed in patients with severe pulmonary edema receiving morphine. Lessening of respiratory effort produces a sudden withdrawal of back pressure (positive pressure) on the pulmonary capillaries. This possibility should be entertained in all cases of serious respiratory disease with increased total pulmonary ventilation before using morphine in repeated or large doses. Bookhamer and Cullen¹⁵⁷ successfully controlled 2 cases of pulmonary edema during anesthesia by intermittent pharyngeal suction and the administration of 100 per cent oxygen under intrapulmonic pressures not exceeding 15 cm. of water.

Carlisle¹⁵⁸ successfully employed positive-pressure therapy in the management of 316 cases of pulmonary edema secondary to exposure to industrial gases, without a single fatality. Barach¹⁵⁹ in his most recent paper once again stressed the value of positive pressure in industrial and war gas poisoning. Blankenhorn¹⁶⁰ stated that oxygen under positive pressure is the best method for managing the

pulmonary edema of gas irritation. Observations in a few patients injured in the Coconut Grove fire in Boston thoroughly convinced me⁷² of its value.

In sudden disasters, when positive-pressure therapy is needed for a large group of people, the temporary procedure of instructing the patient to breathe out through pursed lips may be helpful. Short pieces of rubber tubing with lumens narrower than the human trachea can also be distributed, with instructions to exhale through the tubes. It would be of considerable advantage to the armed forces if the routine gas masks were metered for positive pressure in expiration as is the Barach-Eckman-Molomot mask. In this way if a victim inhaled an irritant gas, he could begin positive-pressure therapy before adequate medical help reached him. Such measures as the above are temporary but may be helpful until proper mask equipment is available.

Tracheotomized Patients

Barach and his associates^{142, 116, 161} demonstrated the value of positive-pressure therapy in expiration in tracheotomized patients. Moore and Binger^{142, 163} previously observed this value experimentally. The pulmonary capillaries become accustomed during expiration to a certain positive pressure, and when this is abruptly withdrawn, as in the tracheotomy patient, an increase in capillary permeability takes place, not only in the alveolar capillaries but also in the secreting glands of the tracheobronchial tree. Oozing of serum and mucus follows.

Woodman¹⁶⁴ showed that breathing against positive pressure during expiration in tracheotomized patients results in the successful management of the profuse edema fluid. He believes this to be due to a carbon dioxide effect. Kernan and Barach¹⁴⁵ confirmed this finding. They easily controlled the clearance of serous and mucous fluid in the tracheobronchial tree by having the patient expire through an elongated tracheotomy tube into a water bottle providing a pressure of 3 to 5 cm. Barach¹⁵¹ outlined the sequence of events in the production of pulmonary congestion and edema in tracheal stenosis. He demonstrated the reversibility of the increasing intrathoracic negative pressures in respiratory obstruction with the use of positive pressures.

In the victim of gas-inhalation, the involvement is largely pulmonary and the proper program to prevent pulmonary edema should be begun at once. The mortality rate in tracheotomized cases of this type is generally high. If tracheotomy must be performed, one should be prepared to keep the opening dry and clear and to apply positive-pressure inhalation therapy with proper humidification through the tracheal cannula.

In general, then, it is best to attempt a program of positive pressure, preferably with a rebreathing hood apparatus, using mixtures of helium and oxygen, before resorting to tracheotomy in cases of

tracheal obstruction, whatever the cause. The number of tracheotomies can in this way be minimized.

Clinical Observations

In employing positive-pressure therapy certain clinical observations are worthy of mention. Many patients find such therapy tiring when the mask is used, and an occasional semiconscious patient at first becomes alarmed at the seemingly increased resistance in the expiratory phase. Reassurance and rest periods can largely overcome this apprehension. When a rebreathing hood is employed, the positive pressure is effective in both inspiration and expiration and the above difficulties do not exist. In the patient desperately ill with serious respiratory disease it is advisable to use either Wangenstein drainage or a Miller-Abbott tube for feeding and decompression, along with positive pressure whenever indicated. The latter can be introduced either through the mask or sleeve of the hood apparatus; it adds materially to the comfort of the patient and enhances his care. I have not observed gastric distention resulting from positive pressure. Free productive coughing and free belching may be somewhat inhibited if therapy is continuous. Positive-pressure therapy should be intermittent, with rest periods of varying time depending on the degree of underlying pulmonary edema. In 2 recently autopsied cases, there were no deleterious effects in the lungs from positive-pressure therapy with pressures up to 4 cm. of water carried on intermittently over periods of two and nine days, respectively.

USE OF HELIUM AND OF HELIUM-AND-OXYGEN MIXTURES

During the last twenty-five years the cost of helium has dropped from \$2500 to 1 cent per cubic foot. The main source of supply is the government-owned Amarillo Field in Texas. Its present volume of production is adequate for its use in the flotation of airships, in medical therapy, for the prevention and treatment of compressed-air illness and in deep-sea diving.

Obstructive Respiratory Disease

Barach made the pioneer observations on the therapeutic use of helium-and-oxygen mixtures. In a series of papers from 1934 through 1944, he described the physiologic basis of its therapeutic value. In 1934, he¹⁶⁵ showed that animals remained well for periods as long as forty days in atmospheres from which all the rare gases had been removed. He also kept mice in sealed chambers in atmospheres of 21 per cent oxygen and 79 per cent helium for periods of two and a half months without harm. He thus proved that rare gases are not necessary for life and confirmed the biologic inertness of helium. Immediately following this, he¹⁶⁶⁻¹⁶⁸ suggested that helium-and-oxygen mixtures be used in conditions

in which there is resistance to the movement of an adequate volume of air to and from the lungs in any part of the respiratory system — namely, bronchial asthma, obstructive lesions of the trachea, larynx and bronchi, emphysema, bronchiectasis and pulmonary fibrosis.

The rationale for the use of helium-and-oxygen mixtures in obstructive respiratory disease rests on the decreased specific gravity of such mixtures and on the fact that the pressure or effort required for the movement of a mixture of 80 per cent helium and 20 per cent oxygen mixture is about half that required for air through similar orifices. In other words, a lighter-than-air mixture flows more easily through a constricted orifice than does ordinary air. During quiet breathing these influences are negligible. With obstruction to respiration, however, an increased negative pressure within the chest becomes necessary for the inward movement of air past the obstruction. Barach demonstrated that it should be possible with helium-and-oxygen mixtures to compensate for approximately a 50 per cent constriction in the lumen of the tubal respiratory tract. The more localized the obstruction the better is the effect, since the viscosity of helium is slightly higher than that of nitrogen. Furthermore, the helium acts as a diluent and vehicle for the oxygen and passes through the constricted orifices to the alveolar sacs.

The percentage of helium and oxygen in the mixture depends on the factors of anoxia and mechanical obstruction. At least 20 per cent oxygen must be used. It is doubtful that helium is of much value if the mixture contains more than 35 per cent oxygen. The Barach rebreathing hood apparatus is the most efficient one for such therapy, but either the Barach metered mask or the B.L.B. apparatus may be used.

The sequence of events that follows resistance or obstruction to inspiration has been summarized by Barach.¹⁵⁴ The resultant pathologically elevated intrapleural negative pressure, pulmonary congestion and interference with left auricular filling and

mann,¹⁷⁷ and Metz.¹⁷⁸ Barach's observations have been confirmed in a series of patients with severe bronchial asthma, gas poisoning, pulmonary edema, atypical pneumonia and postoperative obstructive respiratory disease.^{17, 18, 72}

Boothby and Haines¹⁷⁹ discuss the value of oxygen and helium-and-oxygen mixtures before and after thyroidectomy. One can generally prevent postoperative stridor and postoperative storm and minimize the need for tracheotomy in these cases with helium-and-oxygen mixtures. Kernan and Barach¹⁴⁶ report their effectiveness in cases of obstructive lesions in the trachea and larynx. It appears almost axiomatic to employ helium-and-oxygen mixtures preoperatively and postoperatively in all difficult thyroidectomy cases. Mayo¹⁸⁰ cautions one, however, to remember that helium may mask the stridor caused by an injury to a recurrent laryngeal nerve, and thus prevent the removal of a constricting suture or hemostat.

The value of helium-and-oxygen mixtures in the treatment of asphyxia neonatorum was observed in a paper by Kane,⁵⁶ previously referred to. This observation confirms Barach's earlier expressed opinion concerning their superiority over the conventional carbon dioxide-and-oxygen mixtures. Benedict, White and Lee¹⁸¹ have successfully added helium-and-oxygen mixtures to an infant incubator to combat respiratory failure.

Pulmonary Tuberculosis

Sporadic reports have appeared in the foreign literature suggesting the use of helium in artificial pneumothorax for pulmonary tuberculosis (Reinders¹⁸² and Schedtler¹⁸³). Risen¹⁸⁴ recently made a preliminary report on the advantage of helium as a substitute for air in artificial pneumoperitoneum in the treatment of pulmonary tuberculosis. In a series of cases of pulmonary tuberculosis, periodic injections of 1000 cc. of helium into the peritoneal cavity required considerably greater time for complete appearance than did an equal quantity of

essary. Clough¹⁸⁰ described the use of helium-and-oxygen mixtures in the giving of cyclopropane general anesthesia. Employing a 50 per cent helium, 30 per cent oxygen and 20 per cent cyclopropane mixture, he observed deeper anesthesia and relief of laryngeal stridor. Thomas and Jones¹⁸¹ in an important recent paper discussed the prevention of cyclopropane-and-oxygen explosions by the use of helium. They observed that helium could be used to the best advantage in cyclopropane-and-oxygen mixtures for the prevention of explosions and to a slight advantage in ethylene or ether-and-oxygen mixtures. Bonham¹⁸² stated that helium is a valuable adjunct and diluent for cyclopropane in anesthetic allergy, claiming that all true allergic cases are benefited by the administration of helium. Behnke¹⁸² summarized his extensive experience with the use of helium mixtures in his physiologic considerations of inhalation anesthesia and helium. In anesthesia it is generally considered of value in respiratory obstruction to economize physical effort, to make respiration more effective, to prevent atelectasis, as an aid in partial respiratory failure and to forestall respiratory decompression.

Encephalography

Cleveland and End¹⁸³ summarized their experiences in 41 cases studied in an effort to reduce to a minimum the untoward symptoms after encephalography. They obtained excellent results by replacing the cerebrospinal fluid with helium gas and by following this procedure with inhalation of pure oxygen until all the symptoms subsided. This method produced symptoms lasting less than half as long as those produced by oxygen encephalography and oxygen inhalation and one fifteenth as long as those produced by air encephalography.

Deep-Sea Diving and High-Pressure Work

During the last five years a tremendous literature has developed in the physiology and therapeutics of increased atmospheric pressures. The groundwork for the use of helium-and-oxygen mixtures in the field of deep-sea diving and work under greatly increased air pressure has been laid largely by the United States Public Health Service and investigators of the United States Navy. An excellent historical summary of this series of observations may be found in a recent paper by Shilling.¹⁸⁴ The studies that follow have made it possible for divers to work at greater depths for longer periods of time, have shortened the period of decompression, and have eliminated the toxic symptoms of nitrogen narcosis.

In 1925, Sayers, Yant and Hilderbrand¹⁸⁵ reported their pioneering work in the use of helium-and-oxygen mixtures to ameliorate caisson disease. They wrote:

The substitution of helium for the nitrogen ordinarily present in the air we breathe has been found to result in an atmosphere which is as respirable as that provided by nature. The results obtained indicate that helium not

only has the advantage of being less soluble than nitrogen, but also of diffusing more rapidly in the body fluids and tissues, which results in rapid elimination of the gas from the tissues during decompression. Along with mitigating the hazard of caisson illness helium should markedly increase the scope of other kinds of engineering work in compressed air.

They also demonstrated its value in allowing the decompression time to be shortened from one fourth to one eighth of the time ordinarily recommended for air. Sayers and Yant¹⁸⁶ reported further on the use of helium-and-oxygen mixtures in deep-sea diving and caisson operations.

In 1933, Stewart¹⁸⁷ summarized the status of helium at that time, saying that "divers and caisson workers can work for more extended periods and under higher pressure with greatly increased safety and comfort, and may be returned to normal pressure conditions in a fraction of the time required when compressed air is the atmosphere breathed while at work." He attributed this to the extreme insolubility of helium. Hawkins and Shilling^{188, 189} confirmed this relative insolubility in their studies of the solubility of nitrogen and of helium in blood at atmospheric and increased pressures.

End¹⁹⁰ showed that if helium-and-oxygen mixtures are breathed under a pressure of 3 atmospheres, the subsequent decompression period need be only one third as long as that when nitrogen-and-oxygen mixtures are respired. He also pointed out one of the most important observations of the value of helium in diving; namely, the lessening, and in some cases the elimination, of the untoward mental and neuromuscular symptoms observed under increased air pressure. He stated that "in addition to shortening the time necessary for safe decompression, helium may also free divers from the untoward psychological effects of air at high pressure." In 1938, he¹⁹¹ confirmed these impressions in reporting a world's-record dive of 420 feet in a flexible diving suit while breathing a helium-and-oxygen mixture.

The narcotic effect of greatly increased air pressures has limited the depth that divers can obtain. The limiting depth when air is breathed is generally placed at 300 to 350 feet. The toxic symptoms, ranging from dizziness to loss of consciousness, experienced by all men working in high-pressure air have been described by Behnke and his associates,^{180, 202} Shilling and Willgrube¹⁸³ and others. Behnke and Yarbrough,¹⁸⁴ discussing physiologic studies of helium, state that helium-and-oxygen mixtures minimize or abolish the stupefaction and impaired motor control associated with air respiration under pressure. They¹⁸⁴ found these effects greatest under argon and least under helium. A report on similar work done at the Experimental Diving Unit in Washington, D. C., may be found in a paper by Momsen.²⁰³ Diving tests in depths up to 500 feet were carried out under his supervision. In 1939, a story by Ellsberg²⁰⁴ concerning

helium or diving gas and attesting to its absolute necessity in diving operations appeared in a popular magazine. Additional observations in 300 cases of caisson disease observed at the Queens-Midtown Tunnel project in 1938 and statements on the value of helium-and-oxygen mixtures for rapid and safe decompression can be found in a paper by Thorne.²⁰⁷

Behnke and Willmon²⁰⁸ described the salvaging of the United States Submarine *Squalus*. This monumental work could not have been accomplished without the use of helium. Behnke^{209, 210} described two dives made to the sunken submarine 0-9 at a depth of 240 feet on June 22, 1941. The divers, although subjected to a pressure of 4.3 atmospheres, or approximately 210 pounds per square inch, felt well at the extreme depth while breathing a helium-and-oxygen mixture. In air atmospheres the narcotic effect of nitrogen renders a diver practically helpless at depths in excess of 300 feet. Behnke referred to this condition as nitrogen narcosis, for nitrogen at more than 5 atmospheres pressure is an anesthetic agent. He stated:

It is likely that the fat-solubility ratios rather than the molecular weights of these gases produce the narcotic effect of nitrogen and the benign influence of helium . . . Bends, for example, may be considered as originating from bubble formation in bone marrow, which contains about 90 per cent lipid matter. The lessened influence of bends following long exposures in compressed helium atmosphere is undoubtedly the result of the comparatively low solubility of helium in fat. The tendency to spinal-cord injury bringing about divers' paralysis likewise should be minimized in the helium atmosphere since spinal-cord substance may contain about 27 per cent lipid matter.

The above represents a further advance in the endeavors of the Experimental Diving Unit to increase the scope and depth of underwater activity.

Aero-otitis Media

Armstrong and Heim²¹¹ suggest the term "aero-otitis media" to describe the syndrome of inflammation, discomfort, pain, tinnitus and deafness observed in aircraft pilots during changes of altitude. They attribute this to lack of ventilation of the middle ear owing to failure or inability to open the eustachian tube voluntarily when necessary. Lovelace, Mayo and Boothby²¹² describe the prevention and alleviation of this troublesome syndrome in aviators and passengers by breathing helium-and-oxygen mixtures. They attribute the value of this mixture to the high rate of diffusibility of helium as compared with that by nitrogen. Helium probably diffuses through the sinus ostia or through the eustachian tube more rapidly than does nitrogen. Thus the equalization of pressure between the middle ear and the external barometric pressure occurs more readily. A similar report was made by Lovelace¹ and Henrich.²¹³

Hall²¹⁴ was unable to confirm the above observations of Lovelace et al. He presented experimental evidence that respiration of helium-and-oxygen mixtures during descents at various rates does not sig-

nificantly alleviate the painful ear symptoms resulting from rapid changes in barometric pressure. He demonstrated, however, that slightly greater changes of barometric pressure are necessary to produce the various degrees of otalgia in subjects who descend while breathing helium-and-oxygen mixtures than are necessary in those who descend while breathing atmospheric air. He did not consider the administration of helium-and-oxygen mixtures practical for the prevention of painful ear symptoms.

Chester and Drooker²¹⁵ made a careful investigation of the physiologic changes in the ear during flight. They approached the therapy of aero-otitis media and aerosinusitis by attempting to restore the normal functions of the eustachian tubes and sinuses, thus correcting the pressure gradients. They found most effective cocaine, Neo-Synephrin, the eustachian catheter and politzerization. A similar report is that of Wiseheart,²¹⁶ who employed instillation and suction procedures.

Tubal or Sinus Block

A similar syndrome may be observed when one is going from atmospheric pressure to increased air pressure. Divers generally complain of blocked ears and inability to clear the ears or to equalize pressure. Crosson, Jones and Sayers²¹⁷ observed so-called "tubal or sinus block" among compressed-air workers in tunnel operations in New York City. Employing a small, portable, 80 per cent helium and 20 per cent oxygen, breathing outfit, they obtained immediate relief in 82 of 84 workers. These men were able to re-enter the tunnel and resume their work with no delay or discomfort. Similar observations in compressed-air workers were made by Requarth²¹⁸ and Thorne.²¹⁹ Thorne found helium-and-oxygen inhalations more efficacious than nasal-drop therapy in the management of 306 cases of ear block. He stressed the importance of instituting inhalation therapy as quickly as possible after the onset of symptoms of ear block, for once the firm adhesions of the walls of the eustachian tubes have formed secondary to the existing infection, inhalation treatment is unsuccessful.

Physics of Helium Mixtures

An interesting series of papers concerned with the practical physics of mixtures of oxygen, helium and nitrogen has appeared from the Mayo Clinic. Dublin et al.^{220, 221} made analyses of the percentages of oxygen, helium and nitrogen mixtures by determining the velocity of sound in these mixtures and described an apparatus for doing so.

The voice changes caused by effective helium-and-oxygen administration may be amusing or frightening to the uninitiated. The effect on men can best be described by the term "effeminate." A deep baritone voice develops a lyric-tenor quality, and a man with a tenor voice can only squeak.¹⁹⁰ This

has been explained as due to the fact that the muscles of the larynx are unconsciously set to cause a certain sound in air, and that when breathing a medium so much lighter the sound produced is much changed from normal.²²² Behnke¹⁹² observed that this peculiar nasal quality to the voice does not disappear at increased barometric pressures. The density of the helium-and-oxygen mixture in a pressure chamber can be increased to that of air at atmospheric pressure and the voice still remains abnormal. This renders difficult the problem of communicating with the deep-sea diver by telephone. Divers experienced in breathing helium-and-oxygen mixtures can, however, modify these voice changes to approach the normal.

Dublin, Baldes and Williams²²³ made oscillographic studies on these voice changes. They determined that the alterations consist of a variation in overtones. The frequency of the fundamental vibrations remains the same. The low density of the helium-and-oxygen mixture impedes the vibration of the vocal cords less than does air. This may result in a change in the original production of overtones. Also, because of the lower density, the velocity of sound with helium-and-oxygen mixtures is increased. This probably causes the vocal resonators to amplify different overtones. Which of these differences is more important was not determined.

Behnke and Yarbrough¹⁹⁴ made a splendid contribution from the Experimental Diving Unit of the United States Navy in their paper on the physiologic studies of helium. Their detailed study offered the following conclusions. First, the most striking effect of helium is a feeling of normality, in contrast with the usual intoxication and sense of pressure and depth associated with high pressures. This improved mental condition of the diver is more important than the advantage of shortening the decompression time. Second, the helium content of the body should be about 45 per cent as high as the nitrogen content when the same tension of each gas is breathed. The decreased solubility of helium in fat compared with that of nitrogen theoretically decreases the elimination time of this gas from the body and lessens the possibility of spinal-cord injury. Third, the comparative low fat-and-water solubility ratio of helium compared with that of nitrogen explains the lack of anesthetic effect in helium breathing under pressure as compared with nitrogen breathing under pressure. The latter condition was previously referred to as nitrogen narcosis. Fourth, the helium content of the body is about 40 per cent of the nitrogen content for corresponding gas tensions. At atmospheric pressure 99 per cent of the helium content is eliminated in five and a half hours, or in about half the time required for nitrogen desaturation. Lastly, by periodic determinations of the inert-gas content of the urine a quantitative estimate of gas elimination can be obtained and the occurrence of bends can frequently be prognosticated.

Behnke¹⁹² in discussing the temperature effects produced by helium states that twice as much electrical heat must be supplied to keep a diver warm when he is surrounded by a helium-and-oxygen mixture compared with an air atmosphere. Hardy²²⁴ suggests that the increased molecular motion of helium atoms compared with that of nitrogen results in a greater heat loss from the body through conduction.

Dean and Visscher²²⁵ and Visscher,²²⁶ searching for the physical basis for the therapeutic use of helium, made a study of the kinetics of lung ventilation in dogs. They state that when air movement is turbulent, helium-and-oxygen mixtures move more easily than does air. They found no appreciable difference in the work required to move air or helium-and-oxygen mixtures in animals and in human beings with normal airways and normal lungs. The most significant effect of helium was in reducing the work of moving the gas across an obstruction in the large airways. In going from air to helium-and-oxygen mixtures they demonstrated in laboratory animals with tracheal obstruction a 40 per cent reduction in the work of ventilation. They concluded that helium is useful in obstruction of the upper airways — laryngeal, tracheal or bronchial. These observations were in entire agreement with those previously reported by Barach. They further stated:

Where there is a localized obstruction so that air passes at high velocity through a short, narrow stretch and then can expand into a wider passage where its velocity can be less, under these circumstances turbulence is set up, and therefore substitution of helium for nitrogen in oxygen mixtures is most advantageous in reducing the work of breathing. The mechanism is by increasing the velocity at which there can be streamline flow.

Dean and Visscher conclude further that helium breathing has not been conspicuously successful in uncomplicated asthma, presumably because the obstruction to air flow is in the small respiratory pathways, the bronchioles, and there even nitrogen and oxygen move in streamline flow. The long series previously referred to attesting to its value in bronchial asthma does not bear out the above statement. Furthermore, they state that Barach ignored the factor of viscosity in his earlier explanation of the physiologic basis of inhaling helium-and-oxygen mixtures. In 1935, Barach¹⁶⁶⁻¹⁶⁸ stated in a general discussion at the meeting of the American Society for Clinical Investigation:

A physical basis for the use of helium is as follows: According to Graham's law the rate of diffusion of a gas is inversely proportional to the square root of its density. This law applies also to effusion, that is, the passage of a gas through small orifices, which is especially applicable to the problem here discussed. Since the viscosity of helium is slightly greater than that of nitrogen, there is no reduction in frictional resistance, and Poiseuille's law does not become involved in an explanation of the results. The point involved is that the obstruction exists for a space so limited in extent as to obey the law of diffusion or effusion rather than Poiseuille's law. Under these circumstances the pressure required for moving a mixture of helium and oxygen would be approximately one half that required for moving air. . . . In severe dyspnea the

DIFFERENTIAL DIAGNOSIS

DR. ARTHUR HERTIG*: It seems to me from the history that the differential diagnosis involves some form of pregnancy or some complication of the latter in spite of the fact that the patient was fifty-two years old. Of course it is known that pregnancy can occur in a patient over fifty years of age. In keeping with the diagnosis of pregnancy or of some of its sequelae are the following facts. The patient had perfectly regular periods until she missed two, eight months prior to entry. She then had what she thought was a menstrual period, which, if you look at the record, shows that it was somewhat atypical and could have been anovulatory bleeding from a nonmenstrual endometrium. The character of the bleeding, however, was in keeping with some sort of threatened abortion—intermittent bleeding, sometimes red, and then steadying down to a brownish stain. When this occurs in a younger woman, we believe that it is pathognomonic of threatened or incomplete abortion due to some sort of blighted ovum.

The question comes up whether she had some sort of complication from the preceding pregnancy. Her last pregnancy was twelve years before admission, and some complication is perfectly within the realm of possibility. There are cases recorded in which a chorionepithelioma lay dormant for a great many years and then flared up. I do not believe that this patient had a chorionepithelioma. She had a relatively symmetrical uterus that was enlarged to a size compatible with a four months' pregnancy. It is inconceivable from my personal experience or from anything I have read to have a uterus enlarge symmetrically to that size and be associated with chorionepithelioma.

She could have had a hydatidiform mole which, not only clinically but pathologically, can be defined as a type of temporarily missed abortion. She had a uterus inconsistent with her dates. If she was pregnant at all, she had a four months' uterus, instead of an eight months' one, and such a discrepancy ordinarily rules out hydatidiform mole. Most of us have taught students that all molar uteri are bigger than they should be according to the estimated date of confinement. Actually they may be the same size, smaller or larger.

My diagnosis in this case is a missed abortion of eight months' duration within a uterus that was compatible with a four months' pregnancy. It probably had in it an ovum that was blighted or a dead embryo, the placental tissue of which was living; otherwise a qualitatively positive Aschheim-Zondek test would not have been obtained. It is quite possible, on the basis of our experience at the Boston Lying-in Hospital and the Free Hospital for Women, that she had a placenta accreta as the basis of her missed abortion.

*Pathologist, Boston Lying-in Hospital, and Free Hospital for Women, Brookline.

On the purely gynecologic side, it is possible that she had a single large fibroid, which may grossly simulate a pregnant uterus. Since, however, there is no reason why such a patient would have a qualitatively positive Aschheim-Zondek test, I am forced to conclude that she had a missed abortion, probably associated with a dead fetus, which might not have been visible by x-ray; she may have had a placenta accreta, but probably not. At any rate, she had an enlarged uterus and was in the age group in which, even though she did have a missed abortion, she should have had a hysterectomy, because a missed abortion interrupted from below in elderly patients is not without its hazards.

DR. FRANCIS M. INGERSOLL: I saw this patient in the Out Patient Department, and having just come back from a service at the Lying-in Hospital, I thought that she was pregnant. Since she was bleeding, a pelvic examination was not performed. She had a positive Aschheim-Zondek test, and Dr. Albright's laboratory did the subsequent quantitative Friedman tests. We believed, just as Dr. Hertig did, that it was something related to pregnancy and that the best way to treat the patient, in view of her age, was by hysterectomy, which was performed. Dr. Donald N. Sweeny did the operation. The uterus was symmetrically enlarged, and the broad ligaments were full of varices, but the operation was completed without difficulty.

DR. JOHN L. NEWELL: The fact that on pelvic examination the cervix admitted one finger makes me believe that the patient must have had some labor. With a missed abortion at this stage one ought to be able to feel fetal bones by direct palpation, even if they had become necrotic. By x-ray, however, they would be difficult to see because of gas.

DR. LAURENCE L. ROBBINS: I cannot see anything in the x-ray films that suggests ossification, but as Dr. Newell said, there is sufficient material in the bowel so that it could be missed.

DR. HERTIG: It would not surprise me if the patient had a mole. The story is perfectly consistent with such a diagnosis.

CLINICAL DIAGNOSIS

Chorionepithelioma?

Pregnancy?

Hydatidiform mole?

DR. HERTIG'S DIAGNOSIS

Missed abortion, probably associated with a dead fetus and possibly with a placenta accreta or a hydatidiform mole.

ANATOMICAL DIAGNOSIS

Hydatidiform mole.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The uterus that we received was a large one and was filled with the

grapelike clusters characteristic of a hydatidiform mole. At the time of operation they could be seen extruding from the external os.

DR. JOE V. MEIGS: Are you not surprised, Dr. Hertig, that the titer of the Friedman test was not higher?

DR. HERTIG: It is extremely variable in moles, ranging all the way from total absence of chorionic gonadotropic hormone to 1,000,000 units per liter—a very high titer. The more I see of moles, the less I am surprised about anything that they may do.

DR. CASTLEMAN: There was a fair amount of trophoblastic tissue in the uterus, but no evidence of chorionepithelioma.

DR. HERTIG: I meant to bring out the point that the fact the patient thought she felt a fetus does not mean anything. I remember one case of a mole at the Boston Lying-in Hospital in which the patient, who had had eight or ten children and who therefore knew what fetal movements felt like, was sure she felt fetal movements the day before we operated for a mole.

CASE 30162

PRESENTATION OF CASE

A fifty-one-year-old housewife was admitted to the hospital because of irregular vaginal bleeding.

The patient first menstruated at the age of fourteen. The periods were regular at twenty-eight-day intervals. They lasted five or six days, requiring towels rather than pads. She had considerable discomfort and was forced to remain in bed during the periods. About four months before admission, after having had no menstrual bleeding for six weeks, she began to bleed and continued for seven weeks. She was given ergotrate and "injections" (the nature of which was not known) without relief. There was no tenderness in the right groin. Five days prior to entry she again began to bleed profusely. This persisted. There was no anorexia, weight loss, chills, fever or night sweats.

She had had two full-term normal deliveries at twenty-five and twenty-eight years of age.

Physical examination showed a well-developed, well-nourished, pale woman in no distress. The lungs were clear. There was some tenderness, as well as a suggestive mass, in the lower abdomen. Pelvic examination showed a lacerated perineum, a large, lacerated cervix, which was slightly hard to palpation, and an irregularly enlarged uterus.

The blood pressure was 140 systolic, 80 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood showed a hemoglobin of 6.6 gm. per 100 cc. The urine was normal. A blood Hinton test was negative.

She was given a transfusion of 500 cc. of fresh whole blood.

An operation was performed on the second hospital day.

DIFFERENTIAL DIAGNOSIS

DR. FRANCIS M. INGERSOLL: This case, it seems to me, resolves itself into that of a fifty-one-year-old woman, para II, whose periods have been regular until four months prior to operation, at which time she had a period of amenorrhea for six weeks and then bled excessively, eventually reaching a hemoglobin level of 6.6 gm. Physical examination was negative except for an irregularly enlarged uterus. The average surgeon would have a bit of an advantage because he would do a dilatation and curettage before making a diagnosis. Unfortunately, I cannot do a dilatation and curettage or a pelvic examination under ether to help me establish a diagnosis.

Of course, any patient at fifty-one is either in the menopause or approaching it. At the menopause the ovarian function ceases. This patient may not have been ovulating and may have had anovulatory bleeding, which, however, does not usually result in a hemoglobin level as low as 6.6 gm. I think that we have to postulate a disease besides menopause.

The six weeks of amenorrhea followed by bleeding suggest pregnancy. Pregnancy is infrequent at fifty-one, but we all know that it occurs. If the patient were a younger woman with six weeks of amenorrhea and then hemorrhage, one would think that some complication of pregnancy was likely. She could have had a blighted ovum on the basis of fibroid uterus, which would account for the size of the uterus and possibly for the rest of the picture. That, however, is unlikely, as is a hydatid mole. Chorionepithelioma is a rare disease, and I think that we can disregard it.

A tumor of the uterus might have accounted for the irregularly enlarged uterus and the bleeding, and the first one to be thought of is a fibroid. Fibroids are frequent in postmenopausal women, about one out of every five women at autopsy having fibroid tumors in the uterus. Fibroid tumors in this age group can also cause abnormal massive bleeding, such as this woman had. The mechanism of bleeding in fibroid tumors is not known, but the increase in the menstrual surface may account for the bleeding. It does not seem to me, however, that a fibroid alone could account for this picture. Possibly it was a fibroid, and was one of the 1 per cent that become sarcomatous. If she had a sarcoma of the uterus, one would expect a marked weight loss or other evidence of systemic disturbance that would point toward that type of malignancy.

It is fairly well known that carcinoma of the endometrium is frequently associated with a fibroid tumor. Scheffey,¹ in a paper read before the Boston Obstetrical Society on October 16, 1943, reported

via the uterine vein or plexus of veins going into the broad ligament. One must regard this process as a low-grade malignancy because there was extension outside the uterus. This case is similar to those reported by Frank² in 1932. He called this disease, "fibromyosis"—an unclassified plexiform endolymphatic proliferation of the uterus. In his series

had extended into the broad ligaments. He called it a benign leiomyosarcoma that had invaded the lymphatics.

I recently attended a meeting of the New York Obstetrical Society where Dr. J. Raglan Miller, of Hartford, discussed this condition under the name "stromal endometriosis." He reported 4 cases and considered them benign. At a meeting at Hot Springs, Virginia, Dr. James R. Goodall, of Montreal, told me of his monograph on stromal endometriosis.⁴ The tumors he described involved the stroma, but not the glandular structure. Dr. Goodall thought that if the ovary was removed this tumor would stop growing. At the New York meeting Dr. Frank stated that the tumor was of low-grade malignancy and that he did not believe that it was a stromal endometriosis.

Differential stains show that the supporting reticulum of this type of tumor is not similar to that of fibroids.

DR. CASTLEMAN: It is interesting that this patient also had endometriosis on the surface of the uterus.

DR. HERTIG: I must say that in this case the term "stromal endometriosis" does not seem logical: first, because of the age of the patient and, second, because of the lack of bleeding into the tumor itself.

DR. MEIGS: The patient had no glandular tissue.

DR. HERTIG: It is not the glands that bleed; it is the stroma.

DR. CASTLEMAN: The intravascular growths were purplish red, indicating that there was bleeding into the tumor.

FIGURE 2. Cross Section of Myometrium Showing Intrastromal Fibromatous Plugs.

of 3 cases, 1 patient finally died of metastases and 2 were cured by resection, although 1 had a recurrence. It is not really a leiomyosarcoma because sections do not show true muscle cells; the tumor apparently arises from the endometrial stroma.

DR. MEIGS: In my book,³ a picture of one of these is titled "sarcoma of the uterus"; this, incidentally, is the case that Dr. Hartwell showed you. The lesion

Slaughter, Emma E. Y. (Middlesex North). 545 School Street, Lowell.
Smith, William H. (Suffolk). 8 Marlboro Street, Boston.
Wells, Charles E. (Norfolk South). 15 Union Street, Randolph.

Allowed the following named fellow, applying for retirement, to retire with remission of dues owed the Society under the provisions of Chapter I, Section 5, of the by-laws, such retirement to be effective as of January 1, 1944:

Ledbury, J. William (Worcester). 100 North Main Street, Uxbridge.

Accepted the resignations of the following named fellows, under the provisions of Chapter I, Section 7, of the by-laws, such resignations to be effective as of January 1, 1944:

Ashmore, Buell L. (nonresident). Veterans Administration Facility, Excelsior Springs, Missouri.
Coffin, Betsy (nonresident). Piedmont College, Demorest, Georgia.
Odeneal, Thomas H. (Essex South). 79½ Prospect Street, Gloucester.
Young, David A. (nonresident). 715 Boston Building, Salt Lake City, Utah.
Ziegler, Edwin E. (nonresident). St. Luke's Hospital, Bethlehem, Pa.

Allowed the following named fellow to change his membership from one district society to another, without change of legal residence, under the provisions of Chapter III, Section 3, of the by-laws:

Emmons, Henry M., 354 Commonwealth Avenue, Boston (Suffolk to Norfolk).

Remitted the dues for 1944 of the following named fellows, both of whom are ill and incapacitated, under the provisions of Chapter I, Section 6, of the by-laws:

Krieger, William L. (Norfolk South). 15 Lincoln Avenue, Wollaston.
Sawyer, Alpha R. (Norfolk). 171 Walnut Hill Road, Chestnut Hill.

Reinstated the following named physicians, under the provisions of Chapter I, Section 10, of the by-laws, who had been deprived of fellowship for the nonpayment of dues, provided their arrears in dues at the time they were dropped plus the dues for 1944 be paid to the treasurer of the Society:

Kudish, Benedict (Suffolk). U. S. Quarantine Station, 50 Central Wharf, Boston. Joined 1934. Deprived 1941.

Prenn, Joseph (Suffolk). 15 Bay State Road, Boston. Joined 1908. Deprived 1939.
Savage, Ross E. (Essex South). Masonic Building, Gloucester. Joined 1918. Deprived 1935.
Udelson, Barnett A. (Norfolk). 460 Geneva Avenue, Dorchester. Joined 1934. Deprived 1941.

The personnel of the Committee on Membership is as follows: Harlan F. Newton, *chairman*; John E. Fish; Peirce H. Leavitt; Sumner H. Remick; and Samuel N. Vose. The representatives of the supervising censors are as follows: William H. Allen; H. Quimby Gallupe; and Albert E. Parkhurst.

Executive Committee

DEATHS

HATCH — Ralph A. Hatch, M.D., of Brookline, died April 1. He was in his sixty-third year.

Dr. Hatch received his degree from Harvard Medical School in 1906, and had limited his practice to ophthalmology. He was a member of the Massachusetts Medical Society, the American Medical Association and the New England Ophthalmological Society.

His widow and two sons survive.

LASERTE — Charles J. Laserte, M.D., of Leominster, died April 14. He was in his sixty-third year.

Dr. Laserte received his degree from Baltimore Medical College in 1905. He was a member of the Massachusetts Medical Society and the American Medical Association.

YUDIN — Hyman Yudin, M.D., of Beverly, died recently. He was in his fifty-fourth year.

Dr. Yudin received his degree from the College of Physicians and Surgeons, Boston, in 1918. He was a member of the Massachusetts Medical Society and the American Medical Association.

NOTICES

BOSTON GASTROENTEROLOGICAL SOCIETY

The next meeting of the Boston Gastroenterological Society will be held in the auditorium of the Carney Hospital on Thursday, April 27, at 12 m. The following subjects will be discussed:

Unusual Complications in the Gastrointestinal Tract following Surgery. Dr. William E. Browne.
Polyps of the Bowel. Dr. Timothy F. P. Lyons.
Management of Massive Duodenal Hemorrhage. Dr. Francis J. West.

ANDROGEN CONTROL IN CARCINOMA OF THE PROSTATE*

JOHN P. BOWLER, M.D.,† AND SCOTT F. PEOLEY, M.D.‡

HANOVER, NEW HAMPSHIRE

THIS paper presents a brief report of the early results of castration in 22 cases of carcinoma of the prostate seen during 1942. The physiologic rationale of castration has perhaps been the outstanding item in recent urologic literature, much of which has been controversial and contradictory. With the understanding that many details of the present concept are missing, some not proved and others doubtless later to be changed or disproved, the present basis of attack will be briefly outlined.

Dr. Charles Mayo has been quoted as having made the statement many years ago, "No matter what you do for carcinoma of the prostate, you do the wrong thing." The persistence of this pessimistic attitude has not been without a basis in the poor results generally achieved. Until recently, transurethral resection for the relief of obstruction and radiation for the relief of pain have contributed considerable alleviation, temporary, to be sure, to these patients. The position of the advocates of radical perineal prostatectomy as the only possible direct attack on carcinoma of the prostate is surgically sound, but it fails to meet the general problem, for many reasons. First, the disease originates most frequently in the posterior lamella, thereby giving rise to urinary symptoms relatively late in its development; second, the carcinoma is slow growing and is well advanced by the time that the typical patient of prostatic age, expecting as he does a certain degree of urinary difficulty, decides to obtain medical advice. The most enthusiastic supporters of the radical perineal prostatectomy agree that the percentage of cases to which it can be applied — namely, those in which a malignant lesion is still confined within the prostatic capsule when the patient is first seen — is not over 5 per cent. At least 95 per cent of prostatic carcinomas must therefore be treated by other methods. The importance of the lesion is

brought out by the fact that the number of men living into the prostatic age — that beyond sixty-five — doubled in the United States between 1911 and 1935.¹

Beginning in 1933, Dmochowski,² Kutscher and Wolbergs,³ the Gutmans⁴ and other workers investigating the sources of acid phosphatase in urine discovered that normal human prostate tissue is extremely rich in this material. Acid phosphatase is an enzyme, a constituent of many tissues of the body, but, as noted by these writers and others, it is present in far greater concentration in the adult prostate gland and prostatic fluid than in any other part of the body. Significant is the fact that it occurs in extremely low concentrations in the prepubescent prostate. Most carcinomatous prostate tissue contains large amounts of acid phosphatase, whereas highly malignant tumors, being made up of functionally immature cells, contain but little of it. When metastasis of a prostatic carcinoma occurs, presumably the acid phosphatase is allowed to escape into the blood and lymph and the blood-serum level is elevated. The acid phosphatase is measured in units per 100 cc. of serum, 3 to 5 units being regarded as the range of normal by various workers. Elevated levels may fail to appear because of insufficient invasion, lack of differentiation of the tumor or preceding treatments, as will be discussed later.

Serum alkaline phosphatase is likewise an enzyme, but is less specific than acid phosphatase regarding its prostatic origin. It is elaborated at sites of osteoblastic activity, particularly bony metastases where new bone is being formed. Therefore, Paget's disease and other lesions characterized by osteosclerosis must be excluded if one employs the level of this substance as a measure of osteoblastic metastatic lesions.

It can be inferred, then, that elevation of serum acid phosphatase signifies prostatic-cell activity communicable to the blood stream, therefore of extracapsular prostatic tissue and therefore presumably of carcinoma. Likewise, elevation of the

serum alkaline phosphatase accompanies the change in the metastatic bone lesion from one of osteolytic to one of osteoblastic type, thus indicating sclerosis and regression as a result of a defensive reaction of bone to the tumor.

The findings of Sullivan⁵ and the Gutmans⁶ (Table 1) illustrate clearly the incidence of elevated values in carcinoma of the prostate in the presence of metas-

TABLE 1. *Acid Serum Phosphatase Levels in Various Prostatic Conditions (adapted from Sullivan⁵ and Gutman and Gutman⁶).*

tases. In a series of 200 cases of prostatic carcinoma, 85 per cent of 130 cases with demonstrable bone metastases showed an elevated acid serum phosphatase. Seventy cases without metastases as shown by x-ray examination showed slight elevation in 11 per cent. Glands with benign hypertrophy or prostatitis and normal glands showed no elevation, whereas of 570 cases of nonprostatic disease ten per cent showed elevation, demonstrating extraprostatic origin of acid phosphatase. It is thus evident that the serum acid phosphatase is not elevated in cases of prostatic carcinoma confined to the capsule of the gland. Unfortunately, therefore, such elevation is not corroborative evidence of the nature of the lesion prior to metastatic or extracapsular involvement.

The first investigators to recognize the implications of the results of this experimental research were Huggins and his associates,⁷⁻⁹ who at that time had gone back, so to speak, to investigate the effect of castration or administration of estrogens on prostatic hypertrophy in dogs. On the basis of this work, they published in 1941 an outline of androgen control of prostatic tissue by surgical castration. They reported several cases of metastatic prostate carcinoma subjected to castration in which there was a sharp postoperative reduction in serum acid phosphatase and a rise in serum alkaline phosphatase followed by a gradual decline, and in which these chemical changes were accompanied by marked clinical improvement.

In summary, the rationale of the present approach is the removal of stimulation of the prostate cells by androgen. This is being effected by surgical castration, irradiation castration, neutralization with administration of estrogens and combinations of these methods (Fig. 1).

As shown, surgical castration removed the source of androgen, whereas estrogen may be administered as its neutralizer. In other words, the adult pros-

tatic epithelium is activated by the androgenic gonadotropic hormone, resulting in an increase of the tumor, in an elevated serum acid phosphatase and in the production of symptoms. Castration removes the source of androgen and inactivates the prostatic epithelium, the tumor decreases, the acid phosphatase decreases, and the symptoms decrease. The effect of androgen is similarly neutralized by the use of estrogen.

The use of estrogen as the sole therapeutic program has been reported by Herbst¹⁰ and others as having favorable results, both symptomatically and regarding changes in the gland itself. We have not

FIGURE 1. *Mode of Action of Castration and Estrogen Therapy.*

used it in any case as the sole procedure, but have reserved it for the treatment of delayed recurrences following orchidectomy, with at least temporary beneficial results in several cases.

Irradiation castration has been applied for some years by Munger,¹¹ who seems to think that the results are quite comparable with those of surgical castration. It is highly probable that irradiation castration has in the past been unwittingly accomplished by inclusion of the scrotal field in deep-therapy exposures.

In every case of the present series a surgical castration was done, at times in conjunction with radiation and administration of estrogen in cases in a hopelessly advanced stage. The usual complete castration was performed in the early cases of the series, but in the great majority a subcapsular orchidectomy was done after the manner described by Chute¹² in 1942. Figure 2 demonstrates the procedure. Through separate lineal scrotal incisions, the testicle is delivered from the scrotum. The tunica albuginea is then incised longitudinally opposite the epididymis, and the entire rete testis is removed en masse by instrumental and finger curetting. After ligation of the intracapsular blood supply of the rete, the capsule is closed with a locked suture, the tissues are restored to the scrotum, the skin incisions are

closed, and a suspensory dressing is applied. The capsule of the testis usually fills with blood, which becomes organized, and there is but little change in the palpable or visible contents of the scrotum. The latter advantage appears to be of some importance in the introspective processes of the patient. In this connection it is of interest that we have yet to encounter refusal of this procedure by any patient.

All the cases in this series were those of adenocarcinoma of the prostate gland, proved either by demonstrable metastatic bone lesions or by pathological

third group at the time of operation had received deep x-ray therapy from one to two years previously.

Bone metastasis was demonstrable by x-ray examination in 10 cases, but in only 6 of these was pain given as a symptom. Thus, 4 cases without pain showed bone involvement, whereas in 4 with pain no metastatic extension could be shown. This observation seemed to contradict an old concept that pain in the back, lumbar region or buttocks is complete corroborative evidence of extension of a physically

FIGURE 2. Operative Steps in Castration.

examination of removed tissue. The average age of the patients was seventy years, ranging from fifty-four to eighty-six years. Dysuria was present in 17 cases, an appreciable residual urine in 10, and complete urinary obstruction in 4. An orchidectomy was carried out as the sole procedure in 4 cases; it was done following transurethral resection in 15 cases, and at varying intervals following transurethral resection or prostatectomy elsewhere in 3 cases. The patients in the first group received no x-ray therapy, 3 of the second group received it either previously or combined with the orchidectomy because of the advanced stage of disease, and all 3 patients in the

diagnosable malignant prostate. This concept probably still holds true, but the point to which it leads is that a negative x-ray examination of the lumbar spine and pelvis, like all negative findings, does not justify exclusion of bone metastasis.

This point was forcibly demonstrated by a sixty-seven-year-old patient who had received transurethral resection and deep x-ray therapy elsewhere. The preliminary x-ray films were negative. Two and a half months following the performance of orchidectomy there was extensive osteosclerosis of the third lumbar vertebra and sharply defined areas were seen in both iliums. On review of the preoperative

films by the X-ray Department, fine variations in density could be demonstrated at the sites of these later obvious metastases.

In another case of obvious clinical carcinoma of the prostate, a preoperative bone roentgenogram was definitely negative. Rectal examination revealed characteristic induration and irregularity of the gland. The clinical response of cessation of urinary symptoms was most marked and remained so. On postoperative check-up three months following orchidectomy, roentgenograms showed obvious bone involvement in the right ilium and symphysis.

It is in such cases that the serum acid phosphatase level is of great significance. In 1 such case it was high, showing a preoperative value of 15 units, dropping to 7.8 in the following two months, with a complete stabilization of symptoms that has continued to the present time. Phosphatase determinations are, however, affected by many factors and require a lengthy and painstaking technic, and it has been found necessary to leave this work in the hands of a specially trained technician. At times there has been a disturbing lack of correlation with the clinical course, but we are inclined to attribute this lack to as yet unknown factors of physiologic or pathologic activity.

The serum acid phosphatase level was significantly elevated in 14 cases. One of the highest of these levels occurred in a sixty-four-year-old patient who when first seen was completely disabled, and who was admitted by ambulance, with extensive local and bony involvement and enlarged left supraclavicular nodes that were positive on biopsy. This was one of the most extreme cases encountered. All possible means of therapy were used. A transurethral resection was done because of marked obstruction, deep x-ray therapy was indicated, stilbestrol was given, and an orchidectomy was done. The preoperative x-ray film showed extensive osteoblastic metastases throughout the pelvis. Films taken three months after the orchidectomy showed extreme sclerosing of these areas, which was particularly obvious in the right ilium. By that time there was a 75 per cent recession in the supraclavicular nodes, and the general clinical result was dramatic. This improvement continued for seven months and the patient returned to overseeing his farm. At the end of eight months of normal health, extension and pain recurred, and a rapid progression to a general carcinomatosis followed. This late failure was in contradiction to what was to be expected from the initial clinical picture.

Recalcification of bone following orchidectomy is exemplified in a patient of seventy-seven presenting marked dysuria and bladder irritability, with extensive destruction of the left pubis. Following orchidectomy alone there was almost immediate complete relief of the bladder symptoms, and within a few months there was a dense, smooth and complete

reconstruction of the pubis, with relief of pain walking. This improvement has now continued one year. The patient was one of the 4 on whom orchidectomy only was done, and it is of interest that the results in this small group, as yet unexplained, are uniformly excellent to date.

Response to orchidectomy following relapse after x-ray therapy is illustrated by a fifty-four-year-old patient who was first seen in November, 1941, with obstruction and bony metastasis. Following resection and an intensive course of deep x-ray therapy which included x-ray castration, he was relieved three months. When seen in June, 1942, he was completely disabled. Following orchidectomy he was relieved of all pain and performed general farm work all that summer and fall. Sixteen months after the cessation of the original treatment and months after the orchidectomy, he returned with recurrence and progression, which could not be controlled.

Contrasted with the above case is a seventy-year-old patient who had a similar management before orchidectomy. In March, 1941, he had had a transurethral resection and deep x-ray treatment elsewhere. His complaint when seen by us was recurrent pain, particularly in both thighs, and inability to flex or adduct the right thigh. X-ray films taken two months following orchidectomy showed marked sclerosis of bone. There followed complete relief from all pain and muscular disability, and the patient was able to return to the care of his farm.

We are interested in grading these tumors in relation with the phosphatase activity and clinical variations, but as yet our series is not large enough to permit valid conclusions.

Obviously, more time is required to corroborate our present observations, but the promptness and completeness of symptomatic relief as compared with past methods has been impressive. As yet no other means of therapy for far-advanced cases offers relief for so long or so completely as do the procedures described above. The relief and comfort afforded in cases of remission following routine deep x-ray therapy have been striking. Many carcinomas of the prostate are of low grade and many patients with such tumors live for long periods, and it is much too early to judge the long-time effectiveness of the procedures. On the other hand, these cases present the first tumors available to the clinician in large numbers in which the question arises whether cancer is the result merely of an intrinsic urge of a cell to grow, or the result of a stimulation by substance that may be brought under therapeutic control.

DISCUSSION

DR RICHARD W ROBINSON, Laconia There is little doubt at some of the most dramatic recent occurrences in surgery from the symptomatic point of view, result from castration in advanced cases of carcinoma of the prostate. It appears from the literature that quite comparable results can be accomplished by the neutralization of these androgens through the constant and sufficient use of neutralizing trogen. We should not, however, lose sight of the fact that even in view of the quick relief these patients get from their symptoms, the problem of carcinoma of the prostate not solved by procedures of this kind.

Some months ago Randall reported the end results in 5 cases observed over a period of eight years in which castration had been done for carcinoma of the prostate and in which there were no cures, all the patients eventually dying of carcinoma. I believe that other similar results have been published, and I have recently heard presented facts that indicated that after a period of a year and a half to five years carcinoma progresses in the usual manner or even sometimes in an apparently accelerated one. This being so one would certainly attempt to make a diagnosis of carcinoma with the hope of surgical cure.

Although carcinoma of the prostate, because of its location in the posterior lobe of the gland, does not manifest itself early by urinary symptoms, a yearly rectal examination of patients over the age of forty-five would reveal a great number of carcinomas that would otherwise remain unrecognized until it was too late even to consider a radical total removal of the prostate such as Young advocates.

One of the most interesting questions is why dramatic and quick relief is obtained not only from the pain but also and particularly from the obstructive effects of these large carcinomas. It does not seem possible that within the course of a week or ten days, as so often happens, any change in cellular structure or any regression of a carcinomatous mass could possibly take place. I wonder whether the explanation might not be that some change occurs in the vascular supply of the carcinomatous mass. Perhaps Dr. Bowler or Dr. Pedley can enlighten us on this phase of the subject.

Another interesting point is that there is more than one type of carcinoma of the prostate. Certain types particularly the small celled rapidly growing, malignant one, do not yield to the removal of androgens as do the majority of these growths. It will be interesting to find out whether carcinomas actually developed in the hypertrophied mass of adenomatous prostate yield to the removal of androgens in the same way as does carcinoma of the true prostate. There is considerable doubt whether the benign adenoma that develops a carcinoma in the center of it is of true prostatic origin.

DR ISAAC J ZIMMERMAN, Manchester Dr Bowler and Dr Pedley have made a valuable contribution to this meeting by reviewing the recent work on hormonal control in carcinoma of the prostate and by recounting their experiences during the past year. The discovery of the relation between the androgens and carcinoma of the prostate will always rank as an important milestone along the hard road toward the solution of this vexing problem.

My own experience with the use of castration and of stilbestrol has closely paralleled that of Dr Bowler and Dr Pedley. Clinical improvement is frequently apparent in a matter of days. Objectively the prostate becomes smaller and softer, but usually remains fixed and takes on a peculiar consistence that must be palpated to be appreciated. Its histologically there is actual degeneration of carcinomatous cells.

The effect of stilbestrol on the testis is of some interest in evaluating the mechanism of its eventual effect on prostatic carcinoma, in addition to its neutralizing effect on the androgens. With the co-operation of our pathologist, Dr Robert Biron I have been able to show that the administration of stilbestrol results in changes in the testicle resembling those found following irradiation.

Like Dr Bowler and Dr Pedley, I have not been willing to rely on stilbestrol alone but have given it following castration, hoping in this way to neutralize any androgens that might be elaborated outside the testis perhaps in the adrenal glands.

The subcapsular orchidectomy reviewed this morning is simple to perform, is not disabling and leaves the patient with a reasonably ornamental facsimile. I have found it perfectly easy to do both subcapsular orchidectomies through a single, small, linear scrotal incision.

I might say a word about the effect of regression in the size of the tumor following orchidectomy. The sphincter musculature of the bladder is involved in varying degrees by the carcinoma. Further regression of the tumor with orchidectomy following resection occasionally results in incontinence. It has been my practice therefore where feasible first to castrate the patient, and after the maximum amount of regression has occurred to decide whether tissue ought to be removed and if so how much of it.

It is obvious that, as has been pointed out today, in the short period of two years it is impossible truly to evaluate the long range significance of castration. To the great majority of these patients castration or stilbestrol or both unquestionably bring relief from symptoms and regression of the carcinoma and even of the metastatic lesions. It is therefore, with no intent to detract from the true value of this work and from the gratifying immediate results obtained in the vast majority of the patients that I re-emphasize what Dr Bowler and Dr Pedley have demonstrated in 2 of the cases reported. I refer to the universal experience of seeing with dismay the occasional resumption of the growth of the tumor after a period of latency, and also out and out failures. We must, therefore, temper our enthusiasm with the facts in so far as we know them as Dr Bowler and Dr Pedley have carefully done in evaluating this work. Further, we must continue to be on the alert for early cases of carcinoma of the prostate by doing a rectal examination routinely on every male patient over forty five years of age.

DR BOWLER (closing) There is little that need be added. It is obvious that one has to be extremely guarded to avoid overenthusiasm. On the other hand, the subject is of great interest in connection with any biologic conception of malignancy, in that this is the first tumor occurring commonly in clinical practice in which one can observe and speculate on the relation of malignancy to glandular secretions.

There is no answer at the present time to Dr Robinson's question about the mechanism of the relief that these patients get from their dysuria. Dr Zimmerman in his discussion has explained the matter as well as it can be explained.

SOCIOECONOMIC ASPECTS OF DENTAL CARIES*

A Community and Individual Study of Dental Caries in Selectees

MAJOR ROBERT W. HYDE, M.C., A.U.S.†

WITH THE ASSISTANCE OF CORPORAL DANIEL J. O'CONNELL, A.U.S., AND CORPORAL GEORGE A. LENZI, A.U.S.

BOSTON

IN SPITE of the fact that the study of dental caries lends itself with ease to a broad social approach, comparatively little work has been done with this form of investigation. The examination of selectees for induction into the armed forces includes a dental examination and thus furnishes for study an excellent cross section of the nation's male population of military age. During the first year of induction, dental rejections were reported as the highest single cause of disqualification for military service, with approximately 9.4 per cent of those examined found to possess insufficient teeth to meet the minimum standards.¹ An almost identical high rate of dental disqualifications (9.3 per cent) was found at the Boston Induction Station during the only comparable period. Studies were instituted at this station to determine what community socioeconomic factors were influential in this situation, and it is the purpose of this paper to set forth the results of these studies.

Klein and Palmer² have presented an excellent study of the influence of community socioeconomic conditions on the incidence of dental caries in urban children six to fourteen years of age in New Jersey. The present study concerns a very different group. It appears that the differences in methods and material between the two studies are so wide that if significantly similar results were obtained, it would serve to validate the conclusions of Klein and Palmer that the intrinsic tendency of children to develop dental caries does not depend on the socioeconomic status of the community in which they live, and that the volume of dental care in the form of filling of permanent teeth increases markedly with a rise in community socioeconomic status.

Studies by Britten³ and Collins⁴ showed that frequency of dental service varies greatly with socioeconomic status. Such studies are important only when considered with others showing the variation in dental defects that require dental care, for certain groups with low economic status may not be seeking dental care for the reason that they do not need it.

In none of these studies has any correlation been made between the rate of dental caries and that of dental deficiency of such degree that the subject is unable to subsist on the Army ration. A consideration of the incidence of caries may be far different

from that of dental deficiency of such gross degree, wherein lack of reparative treatment rather than ability to resist caries may be the prime factor.

Classic studies made by Price⁵ and Pickerill⁶ have demonstrated the association of dental caries with the modern diet of civilized man and the almost complete absence of dental caries in all aborigines subsisting on native diets. Little has been shown, however, regarding the application of these studies to the variation in dental caries in the different races and nationalities now living in the United States.

It is not the purpose of this study to delve into the etiology of dental caries, but rather to present certain basic data necessary for the evaluation of preventive methods. Without knowledge of the relation of dental caries to community socioeconomic status and to nationality it is impossible to interpret findings on rates of dental caries.

SCOPE AND METHOD OF STUDY

The present study included the following factors: dental rejections in the examination of 60,000 consecutive selectees from twenty-one to thirty-eight years of age during the winter, spring and summer months of 1942; the decayed, missing and filled teeth in 3899 consecutive selectees from eighteen to thirty-eight years of age examined during a period of 1943; and the dental defects in foreign-born and first-generation Americans of the principal nationalities appearing in the examination of 2400 white and 1212 Negro selectees in a period of 1943.

The selectees were for the most part from urban backgrounds, since they came from the eastern segment of Massachusetts within about thirty miles of the seacoast. On the other hand, there were large enough areas beyond the large cities to make significant the number living in rural and semirural areas, such as would be found on Cape Cod.

The source of the selectees and the socioeconomic classification of the community from which they came were the same as those used in previous studies at this station of allergic states,⁷ tuberculosis⁸ and diabetes.⁹ Hence, the rejection rates of these medical conditions furnish controls for comparison with dental rejections.

The social study was made of each community (local board) from which selectees came, and those factors were evaluated that were considered to be indicative of socioeconomic level. These factors were medical care, educational facilities, social class,

*From the Boston Armed Forces Induction Station.

†Medical director, Medical Section, Headquarters Boston Armed Forces Induction Station.

recreational facilities, public works, undesirably crowded housing and the welfare rate per capita. Each community was given a score on the basis of each of these factors, and the total score was called its "desirability rating." Communities of similar desirability ratings were grouped, so that all the communities fell into a six-category scale of desirability from A in the finest communities to F in the slum areas. For a more complete description of this method of social analysis, the reader may refer to one of our previous studies.⁸

RELATION OF DENTAL REJECTIONS FROM MILITARY SERVICE TO COMMUNITY DESIRABILITY

The dental criteria for acceptance were relatively stable during the period in 1942 wherein 60,000 selectees were examined. For the greater part of the period the minimum requirement was an edentulous upper jaw and sufficient natural teeth in the lower jaw to support a partial denture.

The relation of the percentage of men rejected for military service to the desirability rating of the community from which they came is shown in Table 1. Although this relation is not entirely con-

socioeconomic level. This group, consisting of 3899 men, differed from the previous group of 60,000 in that a greater proportion of men were eighteen to twenty years of age.

Figure 1 shows the average number of decayed (D), filled (F) and missing (M) teeth per person coming from communities of each desirability level, from the best to the poorest communities. The black

TABLE 1. Relation of Percentage of Those Disqualified for Dental Defects to Community Desirability Rating

COMMUNITY DESIRABILITY RATING	No EXAMINED	PERCENTAGE DISQUALIFIED FOR DENTAL DEFECTS
A	6,300	3.8
B	6,100	2.8
C	16,800	4.7
D	12,200	4.6
E	9,400	4.6
F	6,200	5.2

FIGURE 1. The Relation of the Incidence of Dental Caries to the Level of Community Desirability.

stant throughout the range, the percentage of disqualified persons ascends from 3.8 per cent in the best communities to 5.2 per cent in the poorest.

The factors that possibly explain the greater rejection rate in the communities of low socioeconomic standing are less reparative dental care, poorer personal dental hygiene and poorer nutrition. If, however, Klein and Palmer are correct in stating that the incidence of caries is the same at all socioeconomic levels, the increased rejection rate is due to lack of reparative dental care at the lower socioeconomic levels. Hence, it is necessary to know whether dental disqualification from military service is an index of the amount of dental caries or of lack of reparative dental treatment.

RELATION OF TOTAL INCIDENCE OF CARIES PER PERSON TO COMMUNITY SOCIOECONOMIC STATUS

To ascertain the relation of total amount of dental caries to socioeconomic community status and thereby explain the true significance of dental disqualifications, a further study was undertaken wherein the number of decayed, missing and filled teeth per person was counted in selectees in each

bars represent the number of decayed teeth per person found at the time of examination. There is an increase in decayed teeth from 1.5 per person in the best communities to over 3.0 in the poorest communities. Since it is obvious that a decayed tooth is evidence of lack of dental reparative care, it is clear that the need for dental care is present in all communities, but that in the poorer communities the need is twice as great as in the best ones.

The hatched segments indicate the number of filled teeth per person in each socioeconomic level. Here a striking contrast is shown, with about 8 filled teeth per person in the best communities decreasing to about 4 filled teeth per person in the poorest communities. Here can be seen the abundance of dental fillings in persons of every socioeconomic level and their increase with improvement of this level. The number of filled teeth per person appears to be a true representation of the variation in amount of

reparative dental care at different socioeconomic levels, so that it can be considered that dental care is twice as extensive in the best as in the poorest communities. This is in general agreement with the findings of Collins⁴ and of Britten,³ although they approached the problem from the angle of investigating the amount of care received. Our study, however, has the advantage of associating care received with the need for care.

The white segment represents the number of missing teeth per person from communities of each socioeconomic level. There is no significant correlation between the number of missing teeth and community desirability. Since in this respect our findings differ from those of Klein and Palmer,² it remains for further study to demonstrate whether any relation exists between the number of extracted teeth and socioeconomic status. It is certain that in communities where dental care is not easily available the patient prefers to have a tooth extracted to entering on any lengthy course of dental treatment.

The sum of the three segments of the bar represents the average amount of dental caries that each person has had,—that is, the total of decayed, filled and missing teeth,—and is called the “DMF.” Here, quite strangely, the DMF per person in the best communities (17 per person) is greater than that of selectees from the poorest communities (14 per person). If this demonstrates conclusively that the average person in the best communities has had three more carious teeth than the average person in the poorest communities, the fact is of considerable importance. Before any such possibility can be accepted, however, two alternatives must be considered. In the first place, filled teeth may include many caries-free fissures that were filled and that would not have become carious. In the second place, the communities of low socioeconomic level contain a somewhat larger percentage of foreign-born and of races with better teeth than the American average.

If neither of these suggestions proves adequate to explain the increased incidence of dental caries in the better classes, it follows that: the supposedly superior nutrition of the better socioeconomic levels may be poorer nutrition from the dental point of view; that the more extensive personal dental hygiene practiced in the better communities may be injurious; and that the work of dentists may even be responsible for the increased DMF. Perhaps if the findings of Price⁵ and Pickerill⁶ that dental caries is experienced by civilized man on modern dietaries are considered, it can be assumed that the rating of socioeconomic level in this study conforms in some degree to civilization and that the best communities contain persons with more civilized modern dietary habits than those in Group F and hence with worse teeth.

It can at least be said that the people from poor communities have had no more dental caries than do

those from well-to-do communities. This conclusion and our findings on the relation of carious teeth and filled teeth to community socioeconomic level are in accord with the findings of Klein and Palmer.²

This study of the relation of DMF to socioeconomic level shows that dental requirements are so low that the rejections because of dental defects are more indicative of gross lack of reparative dental care than of the amount of dental decay. This shows that dental care is fulfilling a worthy role, but that the role is the repair of teeth, not the prevention of caries.

RELATION OF DENTAL CARIES TO NATIONALITY AND RACE

A study was made of the composition of each community (local board) by nationality. Only those communities were considered in this study wherein there was a predominant nationality. Although a community study of nationality has the intrinsic fault of including a minority of persons of other nationalities, it has the advantage of considering those of the same nationality who have grouped themselves and thus have preserved more of their original culture and habits, including dietary habits, than they would otherwise have done.

Table 2 represents the number of men disqualified for military service because of dental deficiency who resided in communities with a predominant nation-

TABLE 2. *Percentage of Persons Disqualified for Dental Defects from Communities with a Predominant Nationality.*

PREDOMINANT COMMUNITY NATIONALITY	No. EXAMINED	PERCENTAGE DISQUALIFIED
Irish	2440	6.8
English-speaking foreign and old American	1640	4.4
Italian	3472	4.1
Portuguese	2406	2.0
Jewish (Russian)	1869	1.9

ality in the first (1942) study of 60,000 examined selectees. In the Irish communities three times as many persons (6.8 per cent) were disqualified for military service because of dental defects as in the Portuguese (2.0 per cent) and Russian-Jewish communities (1.9 per cent). Since this is a far wider variation in dental rejections than that considered in Table 1, wherein the relation to socioeconomic status is considered, it becomes important to study dental caries in its relation to nationality. As has already been shown in the consideration of DMF and socioeconomic status, the variations in dental disqualifications according to nationality cannot be considered as primarily indicative of caries but rather as showing the proportion of persons with gross dental defects who have not had reparative dental care. With three times as many persons in certain communities as in others having dental deficiency of such a gross degree that it is disqualifying for military service, the need for community planning of dental care is suggested.

The study of the relation of the rate of dental caries to nationality differs from this community study of relation of dental rejections to dominant community nationality in that each person is of the nationality specified, so that there are included persons living in Americanized communities who have lost some of their national dietary habits.

Figure 2 shows the relation of decayed, filled and missing teeth and to nationality by parents' birthplace. A wide variation is seen in all factors. The

FIGURE 2. The Relation of the Incidence of Dental Caries to Nationality.

number of decayed teeth found at the time of examination ranged from an average of less than 1 per person in the Chinese and Russian (Jewish) groups to over 3 per person in the Irish and Portuguese groups. Here, the lack of relation of the number of decayed teeth found at time of examination (D) to the total number that had been decayed at some time (DMF) is especially noteworthy, with the Portuguese and Irish having had very different amounts of decay but nearly the same total number of decayed teeth (DMF).

The number of filled teeth per person also varied greatly with nationality. The Portuguese had the lowest number, 1 filled tooth per person; and the Negroes came next with less than 2 filled teeth per person. Both Negroes and Portuguese also had a comparatively high number of decayed teeth but a low number of teeth that had been attacked at some time by decay. Thus, two peoples with extremely inadequate dental care, as shown by such a high rate of decayed teeth and low rate of filled teeth, had far less dental decay than the average. This again shows that the nationalities having the least dental care may have the least dental caries. Most of the other groups had high numbers of filled teeth: Russian (Jewish), Italian, old American, Canadian,

Irish and English all having on the average more than 4 filled teeth per person.

The number of missing teeth per person appears to bear a rough relation to the number of teeth that have at some time decayed (DMF). It decreases from a high rate of 8.5 missing teeth per person in the English, with a DMF of 17.0 to 3 per person in the Chinese, with a DMF of 6.5. No relation can be seen between missing teeth and either decayed or filled teeth. The only nationality wherein there was a comparatively large number of missing teeth was the Portuguese, with 5.8 missing teeth per person and a low DMF (10.5). This may possibly be explained by the fact that many of the Portuguese come from rural Cape Cod areas, where dental care may be less accessible or the cultural background may be comparatively low.

The total amount of caries that each person had ranged from over 15.5 per person in the English, Irish and Canadians to 10.5 in the Portuguese and Russian (Jewish), 9.5 in the Negroes and 6.8 in the Chinese. As has already been shown in comparing the numbers of decayed and of filled teeth, the total amount of caries is independent of dental care. This wide difference in dental decay in different nationalities is important because it shows the insignificant place of dental care in dental decay and presents a valuable angle of attack on the problem of etiology of dental caries. Furthermore, it shows that prevalence figures must be corrected on the basis of nationality.

For explanation the factors of both heredity and culture require consideration. Either there is an inherent difference in racial susceptibility to caries or there is a difference in the dietary habits of the different races.

Price⁶ and Pickerill⁷ have established beyond doubt that the teeth of aborigines, almost perfect while on their native dietary, become carious when they change to the modern civilized dietary. This suggests that the element of racial susceptibility is entirely secondary to dietary habits, although further study may be required to demonstrate this conclusively.

SUMMARY

Studies were made of dental defects found in the examination of selectees at Boston Armed Forces Induction District and the relation of dental defects to nationality and the socioeconomic background of the communities from which these selectees came.

The incidence of total caries (decayed, missing and filled teeth) per person was found to be highest in the best communities and lowest in the poorest, whereas the number of filled teeth decreased consistently from the best to the poorest communities, reflecting the consistent effect of socioeconomic status on reparative dental care.

The fact that more men from the poorer communities than from the best ones were rejected for

insufficient teeth is more indicative of lack of reparative care than of the amount of dental decay that they had had.

The English and Irish had had the greatest amount of dental decay, whereas the Negroes and Chinese had the least. This fact was not dependent on dental care, since the English had a great number of filled teeth and a small number of decayed teeth, whereas the Negroes had a large number of decayed teeth and few filled teeth. Three times as many selectees from Irish communities were rejected because of dental defectiveness as from Portuguese or Russian (Jewish) communities.

IN VITRO ACTION OF SULFAMERAZINE, PHTHALYLSULFADIAZINE, PHTHALYL-SULFAMERAZINE AND PHTHALYLSULFATHIAZOLE ON ENTERIC PATHOGENS

FRITZ B. SCHWEINBURG, M.D.,* AND I. JACQUES YETWIN, M.D.†

WALTHAM, MASSACHUSETTS

THE sulfonamides have produced clinical results beyond expectation. These drugs were first directed against the septicemias, especially streptococcal and pneumococcal infections. The attention of investigators later centered on infections due to other bacteria, notably those of the pathogenic intestinal group. Relatively little work has been done on the direct effects of the sulfonamide drugs on intestinal bacteria and most of the available literature deals with their clinical effects. The preponderance of clinical studies is justified and is the most important consideration for both patient and practitioner.

In most conditions where the sulfonamides are employed, the blood level of the drug—usually administered by mouth—if kept at a satisfactory concentration for the desired time seems to be responsible for the beneficial effects. The ability of a drug to be absorbed from the intestine in an amount sufficiently high to maintain a proper blood level is especially noted in diseases where a septicemia or bacteremia is manifested. This is particularly true in infections with streptococci, pneumococci, meningococci and the like.

The situation is different when one considers the possible effects of these drugs in infections where the gastrointestinal tract is the main site of the disease or pathologic changes. In such cases one may differentiate two large groups of intestinal diseases: those in which bacteria responsible for the disease are restricted to the intestinal wall, no bacteremia occurring at any time and those in which, in addition to the local intestinal changes, a bacteremia occurs

more or less regularly during certain stages of the disease. No discussion will be attempted of the question whether one has to deal in these cases with a primary bacteremia and a secondary localization in the intestinal wall, or whether primary localization occurs in the intestine and is followed by bacteremia.

In the first group, where bacteria are confined to the intestinal wall, the resultant diseases are caused by the different Shigellas or by *Vibrio comma*. In the group where bacteremia occurs regularly, they are produced by members of the typhoid-paratyphoid group, *Eberthella typhosa* and the Salmonellas. The infrequent intestinal infections with *Bacillus anthracis*, with the Brucellas, with *Pasteurella tularensis* and with *P. pestis* should theoretically be included in the latter group.

It is apparent that the effects of the drugs on these dissimilar groups of enteric infections must depend on entirely different qualities inherent in them. If the bacteria are restricted to the intestinal tract, it is more appropriate to choose drugs that have a slow rate of absorption and remain in the intestine in effective concentration. In the second group, drugs must overwhelm the bacteria in the intestine as well as in the general circulation. Here, a drug with good but not too rapid absorption should be chosen, or even a combination of two different drugs may be administered. One of these should be easily absorbed, thus combating the bacteria in the circulation, whereas the other should be poorly absorbed, thus acting on bacteria in the intestinal lumen and wall.

Aside from the problem mentioned in the preceding paragraphs, the action of the various sulfonamides on the separate pathogenic bacteria should be known in detail. Owing to mutual chemical affinities, even

*Professor of bacteriology, Middlesex University School of Medicine, Waltham, Massachusetts.

†Associate professor of parasitology, Middlesex University School of Medicine.

slight changes in the composition of a given drug may alter its effects on various bacteria; it may become more useful in the destruction of one bacterium and less useful in that of another. It is fully realized that any conclusions drawn from the following experiments can cover only one — and perhaps not the most important — part of the story. Investigations made *in vitro* enable one to determine the immediate effect of a given drug on a given bacterium, but do not decide which drug is most useful clinically in a given disease. The questions of rapid or slow absorption, of producing and maintaining an appropriate blood level and of the rate of drug excretion cannot be solved by test-tube studies.

Experiments of this type may, however, prove useful in cases where several sulfonamides of similar absorption rates are available. They may be especially useful when performed with those pathogenic bacteria that exert their principal or exclusive action on the intestinal tract. So far as the intestinal diseases are concerned, there is apparently no unanimity of opinion concerning which sulfonamides should be used in combating the particular pathogenic bacteria involved.

According to the literature, there is no doubt whatsoever that some sulfonamides are effective against the dysenteric infections. It seems, however, that in infections with bacteria of the typhoid-paratyphoid group the effects of such drugs are not proved, since some difference of opinion on the subject exists.¹⁻⁶ These doubts, together with other reasons, account for the preparation of numerous new sulfonamides in the hope of finding a new compound that will prove effective in cases in which the older drugs have failed. This is laudable work, and any opportunity to evaluate a new drug and to determine its worth against certain bacteria is most welcome. We are therefore indebted to Dr. E. L. Burbidge of Sharp and Dohme, Incorporated, Philadelphia, for supplying us with four new sulfonamides.

So far as we know, only one of these drugs, sulfamerazine, is under clinical investigation; a few reports of its use have already appeared.⁷⁻¹⁵ A similar sulfonamide with two methyl groups, sulfamethazine, has been tested clinically by three groups of investigators, with results comparable to those obtained with sulfamerazine.¹⁶⁻¹⁸ Nothing has as yet been published on the other three drugs. These preparations were obtained during studies on several older well-known compounds for their effects on various enteric organisms. References in this paper are restricted to *in vitro* studies made against the intestinal organisms.¹⁹⁻²⁵

The opportunity has thus been given to compare the effects of the new drugs on certain bacteria with the effects of the older drugs from which they are derived. At the present time all that will be done is to state briefly what the *in vitro* effects of the new drugs are on representative species of intestinal bacteria. Perhaps this will serve to expedite clinical applications that may follow.

MATERIALS AND TECHNIC

The chemical structures of the drugs at our disposal were as follows:

Sulfamerazine is sulfa-methyl-pyrimidine or 2-sulfanilamido-4-methylpyrimidine. It is monomethylated sulfadiazine, but has some characteristics peculiar to the specific compound. Tests show that it is more readily soluble, more quickly and more fully absorbed and less rapidly excreted than is sulfadiazine.⁸

Phthalylsulfamerazine is sulfamerazine to which a phthalyl radical has been added.

Phthalylsulfadiazine is sulfadiazine to which a phthalyl radical has been added.

Phthalylsulfathiazole is sulfathiazole to which a phthalyl radical has been added.

These drugs are crystalline white powders, sparingly soluble in water. Solutions were prepared in sterile nutrient broth. In no case was it possible to obtain clear solutions above a concentration of two per cent. Even at this concentration sulfamerazine and phthalylsulfathiazole did not dissolve readily unless the container was gently heated. In a few cases it was found necessary to heat the stock solution just before use because of a slight amount of sedimentation. It occurred to us that heating might increase the concentration of the drug to a slight extent, but we believed the increase to be negligible. We attempted to minimize this effect by preparing only small amounts of the drugs at a given time.

Since it is known that the solubility of sulfonamides in water — and consequently in nutrient broth — increases with a rising pH, working with strong basic solutions would have been advantageous. But the alkalinity of the solutions was limited by the fact that the medium had to be favorable for bacterial growth. It was decided to maintain a pH of 7.6 in all dilutions throughout the course of the experimentation, using a few drops of 10 per cent sodium hydroxide to aid solution of the drug and to obtain the proper reaction. Lower concentrations were prepared by diluting the 2 per cent solution with necessary amounts of nutrient broth at pH 7.6. Routine solutions were concentrations of 2.0, 1.5, 1.0, 0.50, 0.25, 0.10, 0.05, 0.025 and 0.010 per cent.

The following bacteria were tested in these series: *Escherichia coli*, *Eberthella typhosa*, *Salmonella paratyphi*, *S. schottmülleri*, *S. enteritidis*, *S. suipetifer*, *Shigella dysenteriae* (Shiga), *Shig. paradysenteriae* var. *Flexner*, *Shig. paradysenteriae* var. *Hiss* and *Shig. sonnei*. A standard loop of each bacterium was taken from a twenty-four-hour slant on agar, transferred into 5 cc. of nutrient broth (pH 7.6) and incubated for twenty-four hours. The degree of cloudiness after this period of time varied with each organism.

In order to have approximately the same number of bacteria in all tubes, the twenty-
were standardized with a

elometer tubes were originally standardized against a twenty-four-hour growth of *E. typhosa*. By plating out and counting the ten different strains, it was determined that the nephelometer reading for *E. typhosa* could be used as well for the standardization of the other nine organisms, the percentage of error being practically zero. Consequently, all twenty-four-hour broth cultures were standardized against a tube of the nephelometer corresponding to a count of 16,000,000 bacteria per cubic centimeter. Some slight errors are possible in this method of standardization, but it was thought certain that a few thousand

bacteria more or less would in no way alter the results of the experiments. The findings obtained in the series later proved this assumption to be correct.

A 1:100 dilution of each standardized suspension was made in physiologic saline solution just prior to use. One tenth of a cubic centimeter of this dilution was added to 0.9 cc. of the respective drug dilution, so that each tube always contained the same number of bacteria (16,000 per cubic centimeter). All tubes were incubated for twenty-four hours and read for degree of cloudiness. Following this, appropriate dilutions of the growth were plated out on Endo's agar. After a few preliminary trials it was learned which dilutions were satisfactory in order to obtain a countable number of colonies on the plates. One tenth of one cubic centimeter of the respective dilution was always plated out, two plates being streaked with the same glass rod. In this manner there was regularly obtained a countable number of colonies on at least one of the plates after incubating them for twenty-four hours. As a control, a similar amount of bacteria was inoculated into 0.9 cc. of broth and twenty-four hours later plated out in the manner described above. It was thus possible to discover by comparison any slight bacteriostatic effect of the drug concerned. A sample protocol is shown in Table I.

EXPERIMENTAL RESULTS

The experimental findings are listed in Table 2. The percentage noted in each column reveals the lowest concentration of the respective drug that produced the indicated effect. Each figure represents the average of ten complete trials. Any differences that

were found among the separate trials never exceeded one tube higher or lower in concentration and were exceedingly rare.

DISCUSSION

Several results are apparent from Table 2. Sulfamerazine is effective against *Esch. coli* in vitro in a concentration of 2 per cent; the other three drugs are bactericidal only at concentrations above 2 per cent. The same drug is bacteriostatic for this organism at a concentration of 0.1 per cent, whereas the others fall between 1 and 2 per cent.

Phthalylsulfathiazole is the best bactericide against *E. typhosa*, being effective at 1.5 per cent, and it is bacteriostatic at 0.5 per cent. The other drugs range in bactericidal power from 2.0 to over 2.0 per cent, and in bacteriostatic effect from 1 to over 2 per cent. The superiority of phthalylsulfathiazole over the other three drugs is fully evident.

Against *S. paratyphi* phthalylsulfathiazole is bactericidal at 2 per cent, with the other drugs going above that concentration. For bacteriostatic action, both sulfamerazine and phthalylsulfadiazine are effective at 1 per cent, whereas the others are effective above 1.5 per cent.

Sulfamerazine is the most effective bactericide against *S. schottmülleri*, killing at 2.0 per cent, and together with phthalylsulfathiazole is effective as a bacteriostatic agent at 1 per cent.

Sulfamerazine and phthalylsulfadiazine are equally effective as bactericides against *S. enteritidis* at 1.5

HEMATOLOGY

WILLIAM DAMESHEK, M.D.*

BOSTON

DURING war, research in subjects not directly connected with military medicine must naturally become greatly restricted. Because of this, publications in the field of hematology have been fewer in number, but many of these are of immediate practical value. In line with these new conditions, this year's review will be limited to a discussion of three subjects: blood transfusions and blood substitutes, hemorrhagic diseases and hemolytic processes.

BLOOD TRANSFUSIONS AND BLOOD SUBSTITUTES

The Russian Contribution

Bagdasarov¹ reviews the development of the Russian system of blood storage and distribution, in many respects the forerunner of the blood and plasma banks of today. Perhaps realizing the imminence of a new world conflict, the Russians in 1927 set up the Central Institute for Blood Transfusion in Moscow, with separate decentralized institutes in various cities. By 1932, eighty of these institutes were in active operation for the distribution of blood to the surrounding communities and for active research in methods for the preservation, administration and storage of fresh and cadaver blood. The Spanish Civil War served as a perfect setup for the clinical application of these studies. It was found

that a mixture of citrate and glucose was a better preservative than citrate alone, that the universal donor could be used on a large scale in the front lines without further typing or cross matching, and that undue hemolysis in transportation could be prevented by the use of isothermic containers, which were best transported by the airplane rather than by truck or train. The use of plasma in Russia has lagged behind that in this country and Britain, perhaps because every available soldier and noncombatant at or close to the fighting zone has served as a volunteer donor. The red-cell mass, a by-product of plasma preparation (see below), has been routinely used in cases of severe hemorrhage. A somewhat mysterious note in Bagdasarov's review is that regarding "physiological balanced solutions," which contain a certain amount of plasma in an alcohol-and-glucose-solution base. This cocktail-like infusion is said to reinforce the vital processes, especially when the wounded patient suffers from disturbed hemodynamics not associated with severe blood loss and in septic cases. Although not strictly apropos, mention may here be made of the development by Bogomolets² of A. C. S. (anti-reticular cytotoxic serum), with spleen and bone marrow used as antigenic substances. The resulting serum injected in small doses is said to enhance greatly the immune activities of the reticuloendothelial cells and thus help such diverse conditions as frostbite, slowly

*Professor of clinical medicine, Tufts College Medical School; visiting physician and consulting hematologist, Joseph H. Pratt Diagnostic Hospital.

healing infections, typhus fever and many others. Bogomolov also believes that it may reduce the normal aging process.

Blood Groups, Agglutinins and So Forth

Methods. The use of high titer serum, which is now readily obtainable, should be routine. Serum concentrates,³ powdered serum* and serum and plasma fractions⁴ are all being developed and have their specialized indications. Powders keep well in a wide temperature range and give an extremely quick reaction that can be readily seen on the slide with the naked eye. Since the globulin fraction of serum or plasma contains all the enzymatic factors and antibodies, including agglutinins, methods for its separation from the albumin fraction have been developed. Thus, Pillemet precipitates the albumin with methyl alcohol and concentrates the globulin fraction; the agglutinin content of this material is extremely high. This work has been continued in the laboratory of Dr. E. J. Cohn at the Harvard Medical School under contract with the Committee on Medical Research of the Office of Scientific Research and Development and in collaboration with the Division of Blood Research, Army Medical School.⁵

The slide test is adequate for ordinary typing, but it should not be relied on for cross-matching purposes, since it is relatively insensitive, particularly for weakly reacting and "warm" agglutinins, including the anti-Rh agglutinin. As emphasized in previous reviews, the Landsteiner-Levine test-tube technic is far more accurate and should become a routine procedure.

Under this method, small test tubes (7 by 75 to 100 mm. — that is, Hinton or Kahn tubes) are used. One drop of the serum to be tested, 2 drops of a 2 per cent red-cell suspension and 1 drop of normal salt solution are placed in the tube, mixed and placed in the incubator remaining there for at least thirty minutes. The tube is removed and centrifuged at extremely slow speed for one minute. The "button" may be examined with a hand lens for the presence or absence of agglutination. The tube is then shaken and examined for macroscopic agglutination. Confirmation of the presence or absence of agglutination is obtained by examination of some of the tube's contents on a slide with the low power of the microscope. This method, although seemingly complicated in its description, is readily performed in simple laboratory setups and is sufficiently sensitive for the detection of the great majority of normal and abnormal agglutinins of low titer, including the anti-Rh agglutinin.

The one possible disadvantage of the routine use of the above technic is that it fails to detect cold agglutinins, which have recently assumed some diagnostic importance. This disadvantage may be obviated by performing simultaneous compatibility

tests at either room or, preferably, icebox temperature. For routine transfusions, it matters little whether the recipient's blood contains a cold agglutinin, provided that relatively warm blood is used; however, the finding of incompatibility owing to the appearance of agglutination in the slide-cross-matching technic at room temperature has often held up the use of transfusion in patients desperately ill with acute hemolytic anemia.

Rh agglutigen and anti-Rh agglutinin. The development of knowledge regarding the Rh factor (agglutigen) and its relation to transfusion reactions and to acute hemolytic anemia of the newborn (erythroblastosis fetalis) has made one of the most fascinating and important chapters in modern medicine. This has been duly recorded in previous reviews. The correctness of Levine's original assumption that erythroblastosis fetalis is due to the development by an Rh- mother of an anti-Rh agglutinin, with resultant effects on the fetus's Rh+ cells, has been borne out in at least 90 per cent of all cases. Other agglutinins, or even such physical factors as the condition of the placenta, may have some bearing in a few cases. The failure of some infants born of Rh- Rh+ matings to develop acute hemolytic anemia may depend on the father's genotype: that is, an Rh+ phenotype is made up of either genotypes RhRh or Rhrh. From the latter genotype, the infant may inherit either dominant Rh or recessive rh. If the latter, the union of recessive gene rh with the mother's rh results in an Rh- infant's blood.⁶

The low incidence of erythroblastosis fetalis in Negroes and Chinese led Levine and Wong⁷ to study the incidence of the Rh factor in these groups. Although 15 per cent of Whites are Rh-, only 5 to 8 per cent of the Negroes tested were Rh-, and only 1 of the 150 Chinese tested was Rh-. (It should be pointed out to those who pride themselves on the lack of the "monkey" factor in their red cells that its absence does not necessarily preclude the possibility of the presence of, say, a baboon or an orangutan factor. Studies of human blood for such factors have not yet been undertaken.)

Determination of the Rh factor is of importance in at least three conditions: in pregnancy and childbirth when a transfusion is contemplated for severe anemia or shock, in acute hemolytic anemia of the newborn and in repeated transfusions. In the last if the recipient is Rh-, repeated transfusions of blood, even of the same group, will almost certainly result in the development of an anti-Rh agglutinin; thus, after three to six or more transfusions, the next transfusion if consisting of Rh+ blood may result in a severe and perhaps fatal hemolytic reaction.⁸

For determination of the Rh factor, a potent anti-Rh serum must be available. As yet, such serums are difficult to obtain, because the regular production of potent anti-Rh agglutinin in animals has proved

*Prepared by Lederle Laboratories, Incorporated, Pearl River, New York.

extremely difficult and because high-titer anti-Rh serums are only occasionally found in the mothers of infants with erythroblastosis fetalis. It is advised that each mother of such an infant be routinely tested for anti-Rh agglutinin and that if this is present, even at low titer, she be bled 50 to 100 cc. Concentration of serum can later be performed. Methods for doing this are now in process of development.

The test for the Rh factor is performed by the Landsteiner-Levine technic at 37°C., as above described. It is important to use dilute — 1 to 2 per cent — red-cell suspensions. Levine⁶ and his co-workers have found three types of anti-Rh serum, one agglutinating 87 per cent of the red cells of white persons (anti-Rh₁ and anti-Rh₂), another agglutinating 85 per cent (anti-Rh₁) and the third agglutinating 73 per cent (anti-Rh₂). Since the last serum gives 27 per cent negative reactions, the significance of an Rh— determination in a given case is open to doubt. Thus, unless a laboratory has a highly potent anti-Rh testing serum, it is important to perform a careful compatibility test of the recipient's serum with the prospective donor's red cells. To do this, the time of incubation should be prolonged to one hour. Boorman, Dodd and Mollison⁹ suggest a modification of Levine's technic, which they state brings out more clearly the anti-Rh agglutinin. These workers allow the mixture of recipient's serum, donor's red cells and normal salt solution to remain in the incubator for two hours. The pattern of the sediment is then examined with a hand lens and a portion is pipetted off for microscopic examination. They state that the manipulation of the blood involved in centrifugation and shaking may abolish a weak reaction. If such tests are negative, the transfusion may be given with almost complete safety. The reservation must nevertheless be made that even with a completely negative in vitro test, there may be an in vivo hemolytic reaction. The only possible way to obviate this completely is to set up a list of well-established Rh— donors for use in the three conditions referred to above — that is, in women in childbirth, in cases of erythroblastosis fetalis and with repeated transfusions. It is almost essential to use nothing but Rh— blood in infants with acute hemolytic anemia, since transfusions are the only treatment, and the introduction of Rh+ cells may result in the combination with any still present anti-Rh agglutinin derived from the mother.

Cold hemagglutinins. The antigen-antibody reaction between human red cells and serum that is observed chiefly or solely at temperatures below 20°C. is called "cold hemagglutination." Cold agglutinins in low titer are commonly present. Thus, Kettel¹⁰ found them in 95 per cent of normal subjects, and more recently Shooter¹¹ in examining 4710 serums observed that 32 per cent showed these antibodies at 5 to 7°C. Cold agglutinins sufficiently strong to be active at room temperature were found,

however, in only 29 of 10,000 serums. Low temperatures at times activate or bring to light an otherwise weak agglutinin; this is reminiscent of the Donath-Landsteiner phenomenon — the activation by cold of the abnormal hemolysin of paroxysmal cold hemoglobinuria. The subject of cold hemagglutination is an old one, having been discussed by Landsteiner in 1903 and more fully by Landsteiner and Witt in 1926.* Although cold hemagglutinins have been observed in such diverse diseases as cirrhosis of the liver, hemolytic anemia of the acquired type and infections due to spirilla and trypanosomes, interest in this subject has been considerably enhanced in the past year by the finding of such agglutinins of high titer in primary atypical (virus ?) pneumonia.^{13,14} The initial hope that this antibody would prove of diagnostic importance in the differentiation of atypical and other pneumonias has proved only partially correct, since a fairly high titer is present initially in only about 50 per cent of all cases. The titer of agglutinin frequently increases with progression of the disease and may not reach its peak for seven to twenty-one days.¹⁵

The cold hemagglutinin appears to be quite distinct from the normal blood agglutinins, since it agglutinates all human red cells, even those of Group O, and may agglutinate those of a number of animals — that is, "pan-agglutinin." Because it also has the property of agglutinating the red cells of its own blood, — at least in the test tube, — the term "autoagglutinin" has often been used. This, however, is only partly descriptive and it is probably best to use the more general term "cold hemagglutinin."

Aside from its purely diagnostic significance, the cold hemagglutinin has recently assumed considerable clinical importance. Thus, certain cases of acute hemolytic anemia occur at times in association with primary atypical pneumonia. Usually the sulfonamide drugs have been administered and it has been customary to ascribe the hemolytic reaction to the drug. Whether or not this is correct, when a transfusion is considered for the severe anemia and blood-grouping tests are done, it is often found that all prospective donors are incompatible. This is of course due to the presence of a cold agglutinin in high titer with resultant agglutination — at room temperature with the ordinary slide technic — of the red cells of all blood groups. For this reason, transfusions have often been delayed or not given at all in patients desperately needing them. In such an event, the matter is quickly resolved by performing the cross matching at incubator temperature by the test-tube technic described above. I¹⁶ have also recommended in such cases the use of blood that is kept warm from the time of its removal from the donor to its entrance into the blood stream of the recipient.

*For an excellent review of the entire subject of the cold hemagglutinins the reader is referred to an article by Stats and Wasserman.¹²

The cold hemagglutinin in these cases is also important from the standpoint of chilling of the patient. Thus, marked acrocyanosis and beginning gangrene of the nose, ears and fingertips have been recently described in association with primary atypical pneumonia and a high titer of cold agglutinin.¹⁷ The cold agglutinin may persist for months¹⁸ or perhaps years following an attack of atypical pneumonia, making the person who harbors it liable to the development of hemoglobinuria, chronic hemolytic anemia, extreme coldness and blueness of the extremities or even gangrene on exposure to extreme cold. In a case under study at the present time, all these symptoms have been present since an attack of pneumonia two years ago.¹⁸ Two or three further attacks have occurred in the interim. The cold hemagglutinin is present in a titer of 1:128,000. Because of the presence of a chronic hemolytic anemia with splenomegaly, it is likely that this patient has considerable *in vivo* autoagglutination, which is enhanced by exposure to cold. Stats and Bullowa¹⁹ report a somewhat similar case in which symmetrical gangrene of the tips of the extremities occurred with exposure to cold. This patient did not have a hemolytic process, but the *in vivo* agglutination of red cells could be demonstrated by introducing ice water into the conjunctival sacs and examining the bulbar and palpebral conjunctivas with the slit-lamp corneal microscope.

From these and other observations several conclusions may be drawn. First, patients with primary atypical pneumonia should under no circumstances be chilled. Second, if a transfusion becomes necessary because of an acute hemolytic reaction, the cross matching should be done by the test-tube technic at incubator temperature. Third, warm blood should be used and the apparatus, tubing and so forth should be kept constantly as warm as possible. Cold blood withdrawn from the refrigerator should not be used, certainly not before proper warming.

Transfusion Reactions

Severe and often fatal transfusion reactions still occur all too frequently. Exact statistics on their incidence are almost impossible to obtain because most of them go unreported. They are probably as frequent as they are because blood grouping is often relegated to inexperienced persons with little awareness of the great responsibilities involved in correct typing and cross matching. The development of a fatal transfusion reaction in a relatively healthy young person who is being prepared for an elective operation is a tragic event that is in many cases due to omission of either the typing or the cross-matching test. Each transfusion should be preceded by careful cross matching of the recipient's serum with the prospective donor's red-cell suspension and by typing of both the recipient and the prospective donor, except under very special circumstances, it is not

necessary to do the so-called "minor agglutination" — that is, the donor's serum versus the recipient's red cells. If the same blood groups are used, no agglutination with the donor's red cells will occur. If a Group O donor, for example, is used for a Group A recipient, the resultant agglutination with the donor's red cells is to be expected because members of Group O have anti-A and anti-B agglutinins in their serums.

As noted above, cross matching should preferably be done by the test-tube technic at incubator temperature and for at least thirty minutes. This has recently been made an official recommendation of the (British) Medical Research Council.²⁰ If an unusual emergency exists and thirty minutes seems too long a period to wait, blood plasma should immediately be given.

A transfusion reaction is best treated by its prevention. The intern or technician who performs the test must be acutely aware of the important responsibility involved — literally one of life and death. Even in an emergency, carelessness and too much hurry are inexcusable. Even with all precautions carefully observed, a severe reaction occasionally occurs, that is, the *in vivo* biologic test is at times more accurate than any form of *in vitro* testing. For this reason, the recipient should be carefully watched, particularly during the administration of the first 50 to 100 cc. of blood. If there is any complaint whatever of pain in the back or flanks, pain down the legs, a smothering sensation, a burning sensation in the face, a sense of constriction, a chilly sensation or chill or even a sense of something wrong, the transfusion should be immediately discontinued. These symptoms are usually indicative of intravascular agglutination. Whereas the recipient can usually survive the administration of 50 to 100 cc. of incompatible blood, the agglutination of 500 cc. of blood is usually fatal. The investigation of the causes of a severe hemolytic transfusion reaction is described by Mollison.²¹

Red Cells from Bank Blood

The great developments in the use of plasma resulted in almost complete ignoring of the mass of red cells, which were almost routinely discarded. Many observers, however, have remarked on this great waste in a valuable by-product, and in recent publications suggestions for its use have been made. The British workers MacQuaide and Mollison²² and Williams and Davie²³ used the red cells for the treatment of anemia. Bagdasarov,¹ the director of the Russian Central Institute for Blood Transfusion, reported in 1942 that the red-cell mass was best preserved at 4 to 6°C. with a solution containing magnesium sulfate, potassium chloride and sodium chloride; no marked change in red cells occurred up to twelve days. The red cells were found of great value in cases of severe anemia following blood loss. Watson²⁴ pointed out that by the use of a

cell suspension one could rapidly increase the oxygen-carrying capacity of the blood with a minimum of introduced solution. This was particularly useful in ambulatory patients and in certain cardiac patients with anemia. Alt²⁵ stated that the main value of red-cell transfusions is to increase the erythrocyte count in patients with anemia, particularly following severe hemorrhage. Other suggested uses are in patients with severe iron deficiency and in progressive refractory anemia — that is, in cases with bone-marrow disease due to aplasia, leukemia, tumors and so forth. Because red cells in suspension may be given in concentrated form, larger numbers of them can be given at one time and more frequently than with the use of whole blood. Litwins²⁶ has suggested the use of Group O red cells admixed with pooled plasma to form a completely universal Group O blood — that is, one containing no agglutinogens and more or less completely neutralized agglutinins.

A new use for preserved red cells — the promotion of normal healing — was suggested by Moorhead and Unger.²⁷ Seldon and Young²⁸ state that such red cells either from a single or from different blood groups, when mixed together and stored in a refrigerator for days or weeks, form a gelatinous mass that may be used as a dressing material for wounds, burns, ulcers and chronic infections. This was found of distinct value in the promotion of growth of vascular and connective tissue in the injured surfaces. Because of the difficulty of keeping the semiliquid red-cell material in contact with the wound, Seldon and Young dried it and used it as a fine sterile dusting powder applied directly to the wound surface. Infected wounds, poorly healing postoperative abdominal wounds, certain proctologic cases, varicose and other ulcers of the leg and amputation stumps have been successfully treated. The method seems to offer distinct possibilities in the treatment of healing wounds.

Because of these two developments, the formerly discarded red-cell by-products of the blood bank are now of distinct value; this applies to the treatment of severe anemia, particularly when the regenerative capacity of the bone marrow is impaired, and in the promotion of better wound healing.

Blood Substitutes

Liquid plasma. Liquid plasma when prepared under completely aseptic precautions has been stored at room temperature for a year and a half or longer.²⁹ During this time, it loses none of its protein or colloidal osmotic value, but there is a rapid loss of antihemorrhagic factors, such as prothrombin, and of complement. Newhouser and Lozner²⁹ state: "The permissible temperature range of preservation probably lies between 15 and 30°C. (59 and 86°F.). Below this range excessive fibrin precipitation may occur, and above this range protein denaturation occurs rapidly."

The chief advantage of pooled liquid plasma is its ready availability. It may be taken off a shelf and without further testing, reconstituting or other steps be given immediately to a patient in shock. The intravenous set should contain a suitable filter to hold back particles of fibrin. The chief disadvantage of liquid plasma is that it is an excellent culture medium for the growth of bacteria; hence, unless plasma is scrupulously prepared, preserved and tested for sterility, it may well become infected.

Plasma may be given in so-called "units" of 250 cc. each; the recent tendency has been to give larger doses than 1 unit. Thus, 4 units (1000 cc.) may be given without danger, although due consideration should be given to the relatively large amounts of sodium and citrate that are introduced. A caution against the too liberal use of citrated blood was recently voiced.³⁰ Citrate may be quite toxic, although the toxicity depends to some extent on the rate of injection. Five grams of citrate given intravenously may be considered as a safe maximum, since 15 gm. has been shown to be fatal. Since 50 cc. of a 2.5 per cent solution (1.2 gm.) is customarily used for 1 unit of plasma, this indicates that more than 4 units of plasma, or 1000 cc., should not be used. A citrate reaction³¹ which may result in tetany owing to the binding of calcium, is characterized by the development of a positive Chvostek sign, a general tingling sensation, dilatation of the pupils and, finally, actual clonic twitching. The reaction can be quickly terminated by the intravenous injection of calcium chloride or gluconate.

Frozen plasma. Liquid plasma may be preserved in the frozen state in special refrigerators that maintain a constant temperature of -15 to -20°C. Under such conditions, there is indefinite retention of the various thermolabile constituents of the plasma. Reconstitution from the frozen state requires about thirty minutes at a temperature of 37°C., the bottle being placed in a water bath, not an incubator. According to Newhouser and Lozner,²⁹ the best results in thawing are obtained by this method, followed by maintenance for two to three weeks at room temperature. Quick thawing may be followed by a cloudy plasma.

The chief advantages of frozen plasma lie in the maintenance of sterility and the preservation of immune bodies and antihemorrhagic and other factors. The sterility factor alone has been emphasized as of the greatest importance. The disadvantages of freezing lie in the use of a special, rather expensive freezing unit; the necessity for slow reconstitution (thawing), making it imperative to wait for at least thirty minutes, sometimes a long time in an emergency; and the occasional breakdown of current or apparatus, with consequent thawing. These disadvantages can all be obviated by appropriate measures, some of which are covered by Newhouser and Lozner.

Dried plasma. This material, prepared by dehydrating liquid plasma by one of several processes, can be quickly reconstituted by the addition of pyrogen-free distilled water. It contains in unaltered form both albumin and the various thermolabile globulin constituents of the previously liquid plasma and, what is more, preserves them for many months without appreciable loss of activity. It has a wide range of safety with regard to temperature and bacterial contamination. It should not, however, be allowed to freeze or to stand for any length of time at a temperature above 55°C.²⁹

The unusual value of dried plasma in shock and cerebral accidents was quickly recognized: it could be reconstituted in relatively small amounts of fluid, thus obtaining a hypertonic material which would draw unusual amounts of plasma into the circulation and simultaneously dehydrate certain swollen tissues, such as an edematous brain. The use of two-times, four-times and five-times concentrated plasma has been advocated as a routine measure by various investigators. With twice-concentrated plasma, 250 cc. of water can be used to reconstitute the dried material obtained from 500 cc. of plasma. This is probably more effective in shock than is isotonic plasma, and furthermore adds to the circulation at once an adequate amount of protein. Four-times or five-times concentrated plasma possesses the diluting function in even greater fashion than the twice-concentrated material. Erf and Jones³² dissolve the dry material obtained from 500 cc. of whole blood in 60 cc. of water, which is given by syringe rather than by gravity, as is customary when amounts over 50 or 60 cc. are used. They claim that this is a far quicker and more readily available method, especially for use on the battlefield, than is the gravity-tubing-filter method. Heyl and his collaborators³³ state that the viscosity of concentrated plasma because of the presence of the globulins is much greater than that of concentrated albumin (see below). The total osmotic pressure is furthermore greater because of the presence of concentrated electrolytes; however, the colloid osmotic pressure is less than that of concentrated albumin solutions.

Thus, dried plasma has many advantages: its availability at almost any temperature; its elasticity with reference to the amount of solution that need be added, thus allowing complete control of the degree of desired colloid osmotic pressure; and its retention of sterility under almost any conditions. Its possible disadvantages lie in its use in too highly concentrated form: here if the patient is dehydrated, there may be further drying of various tissues while the blood volume is becoming increased. Furthermore, in a patient with myocardial involvement, the rapid increase in blood volume may impede the circulation.

Dried plasma has its greatest usefulness in shock and related states. It is of value in other conditions as well: in hypoproteinemia, especially with edema, to add protein; in certain conditions of local edema,

as in the brain and the extremities, when other methods of therapy have failed; in chronic or acute nephritis as a diuretic, even in the absence of hypoproteinemia; and in severe hepatitis, particularly in the presence of a reduced blood protein and ascites. It would probably be even more widely — and perhaps unwisely — used in civilian practice than it is at present were it less expensive. Sufficient dried plasma for the military services has fortunately been supplied by volunteer donors, with the invaluable assistance of the Red Cross and of various pharmaceutical houses.

Human albumin. Plasma is a highly complex solution. It not only contains proteins that are essential for its own stay in the circulation but has all the various hormones, enzymes, metabolites and so forth that are in process of transportation from one tissue to the others. It has been customary to divide the plasma proteins roughly into two fractions: albumin and globulin. The albumin fraction is relatively pure, but the globulin fraction is composed of a large number of substances that differ greatly from one another with respect to their chemical structure and their function. Although great strides have been made in studying these complex proteins, it is probably safe to say that thus far only the surface has been scratched. Two of the important tools in studying the plasma proteins are the Tiselius apparatus for the observation of electrophoretic mobilities and the ultracentrifuge.

The task of purification and fractionation of human and animal plasmas for military use has been undertaken by the Department of Physical Chemistry at the Harvard Medical School, under the direction of Professor E. J. Cohn. Disregarding respiratory, hormonal and enzymatic proteins, the plasma proteins may be divided according to Cohn³⁴ into those concerned with clotting of the blood, with complement, with immune processes, including antibody and antitoxin, and with water and electrolyte balance. Among those that have thus far been identified are fibrinogen and prothrombin and the "mid-piece" and the "end piece" of complement. The bulk of the various globulins comprising the globulin fraction of plasma has thus far not been separated in pure form; they have been characterized either as cuglobulins or pseudoglobulins or — in terms of their electrophoretic mobilities — as alpha, beta and gamma globulins. In general, the globulins have an extremely high molecular weight and on that account exert a smaller osmotic pressure than do the smaller molecules of albumin. The separation in relatively pure form of the simpler albumin fraction from the complex globulins has been effectively accomplished by Cohn and his collaborators.³⁴

The albumin thus prepared and freed from the more labile and more readily denatured fibrinogen and globulins is readily soluble in water, yielding clear solutions even at concentrations containing as much as 70 per cent of albumin by volume. Even in

concentrated form, albumin solutions have a lower viscosity than has plasma, interact only slightly with other proteins and salts and stand up under conditions of extreme heat and cold.²⁹ They furthermore exert a much greater colloid osmotic pressure than does whole plasma. For these reasons and because of their immediate availability for intravenous injection, albumin solutions have proved extremely useful in the treatment of wound shock. The standard Army-Navy package of concentrated human-albumin solution consists of 25 gm. of albumin in 100 cc. of buffered salt solution, supplied in a large ampule ready for instant injection by gravity through an ordinary 19-gauge or 20-gauge needle.²⁹

Heyl, Gibson and Janeway³³ have calculated that each gram of albumin injected intravenously adds by osmotic pull 18 cc. of fluid to the circulation. These calculations, when subjected to actual experimentation in the human subject, were found to be surprisingly accurate; thus, the actual increment in plasma volume varied from 13.2 to 24.0 cc. in all experiments, with an average value of 17.4 cc. The use of 25 gm. of albumin is thus approximately equivalent to the administration of 450 cc. of normal circulating plasma or 500 cc. of citrated plasma as usually prepared.

Hence, a concentrated solution of purified albumin possesses many advantages. Certain disadvantages must also be assessed. Because of its very great osmotic pull, there is a danger of dehydrating vital tissues, especially in soldiers and others who have been exposed to many hours of struggle under conditions of extreme heat and thirst. For this reason, the use of albumin solutions should probably be restricted to hydrated or only slightly dehydrated persons. Another disadvantage of albumin solution is its lack of globulin substances and thus of enzymes, blood coagulating materials and antibodies. The administration of several injections of albumin solution has furthermore been found to result in a modification of the albumin-globulin pattern of the plasma, with possible effects on immune reactions.³⁶

Indications for albumin solution are thus relatively few, and depend entirely on its great colloidal osmotic pull. It is useful in shock and in conditions associated with hypoproteinemia and edema. As yet, it is not available for civilian use; even if it were, its cost would probably render its use almost prohibitive. Partly for this reason and also because of ready availability, the preparation of albumin from animal sources has been given much thought.

Bovine albumin. Cohn and his collaborators³⁴ have shown that human albumin and bovine albumin present remarkably similar molecular patterns from a physiochemical point of view. Both by means of the ultracentrifuge and the Tiselius electrophoretic apparatus, the two albumins are to all intents and purposes indistinguishable. The chief difficulty, however, is not the physicochemical one but rather the immunologic reaction. This probably develops

because of slight contamination of albumin with globulin. The matter of development of sensitivity to a heterologous material is of great importance and has been studied by Janeway³⁶ and by Heyl, Gibson and Janeway.³³ The latter authors came to the following conclusion: "No statement regarding the safety for intravenous use of crystallized bovine serum albumin of low globulin content can be made until more extensive clinical tests have been completed in order to determine to what extent and under what circumstances it will be safe to use a protein of animal origin for therapy in man."

Sites of Administration of Blood and Blood Substitutes

The preferred site of administration of whole blood, plasma, and the various blood substitutes is naturally in the various large veins, which are usually readily found in the antecubital fossas. In extreme shock and in extensive burns, these veins may either be collapsed or inaccessible. It is well, therefore, in emergencies to have in mind the possibility of administering these substances in other than the basilic veins.

The femoral vein is not customarily thought of in this regard, but its use might well be increased. The vein is extremely large and is situated just medial to the femoral artery, which is readily palpated in the inguinal region. With a little practice, puncture of the vein is readily performed. Administration of plasma by this route was found extremely useful by the Boston City Hospital group during the Coconut Grove fire disaster in 1942.

The infusion of blood and other fluids by way of the sternal marrow was suggested by Tocantins³⁷⁻³⁹ in 1940 and has gradually assumed increasing value. Tocantins demonstrated by careful injection experiments in cadavers, and later by clinical studies in animals and human beings, that substances injected into the marrow cavity are immediately taken up into the venous circulation apparently unchanged. In adults, the marrow cavity of the sternum is readily entered by the introduction of a sternal-puncture needle—an abbreviated stiff lumbar-puncture needle will do—through the skin and subcutaneous tissue and through the anterior lamella of the sternum. The procedure, which is done under novocain anesthesia, is a simple one and is readily learned. A sensation of give is felt when the needle enters the marrow cavity. The stilet is then withdrawn and a small amount of marrow is aspirated. An adapter may be attached to the needle and to rubber tubing and a gravity device, or the blood or fluid may be introduced under positive pressure by means of a syringe. If the injection of more than 50 cc. is contemplated, it is wise to use a two-way stopcock and thus avoid removing the syringe from the needle for each 50 cc. As Tocantins states, rapid injection—over 20 cc. per minute—may be accompanied by a sense of pressure or grinding pain.

similar to that of angina pectoris, this quickly disappears at the termination of injection. It is, however, rarely necessary, or even advisable, to inject fluids at such a rapid rate. The use of the intrasternal route is particularly applicable to military medicine, and a number of reports from military establishments in which its use is favorably commented on have appeared.⁴⁰⁻⁴¹ In one such report, the sternal-puncture needle was allowed to remain in situ for three or four days, with occasional cleaning, 14,000 cc of blood and fluid was given with no untoward effect.

The marrow may also be used for the introduction of fluids and blood into the infant's circulation. Tocantins's studies have shown that in the newborn and in early infancy the marrow cavity either above or below the knees is best utilized. In older children, aged two to four, the mid-tibia may be better. Above the age of four, the sternal cavity is fairly well developed and thus available for injection.

(To be concluded)

CASE 30171

PRESENTATION OF CASE

A fifty-nine-year-old housewife entered the hospital because of a bearing down sensation in the pelvis.

The patient was in good health until three months before admission, when she noticed "something falling into the vagina" whenever she stood up or walked around. On examining herself she found a small lump in the vagina. These symptoms persisted. She had had no nocturia, vaginal discharge, incontinence, increased frequency or bleeding.

She had had tuberculosis at twenty-nine and passed five years in a sanitarium, at which time she had a phrenectomy. At fifty she had a pulmonary hemorrhage and stayed in bed for two years. She had had a right nephrectomy for renal tuberculosis eight years prior to admission. She had had occasional indigestion over a period of many years without known nausea, vomiting or diarrhea. The menopause occurred at fifty-one.

Physical examination showed a well-developed, obese woman in no distress. There was dullness over the right lung posteriorly and over the left apex, with coarse rales throughout. The heart was normal. Tenderness was elicited over the nephrectomy scar. Pelvic examination showed a rectocele and a cystocele.

The blood pressure was 150 systolic, 75 diastolic. The pulse was 100; the temperature and respirations were normal.

Examination of the blood was normal. The urine was normal. A blood Hinton test was negative.

X-ray examination of the chest showed evidence of inactive tuberculosis in both lungs. An intravenous pyelogram showed a normal left kidney. The right kidney was absent.

On the fourth hospital day a vaginal hysterectomy and a perineal repair were performed. After the first ten minutes there was a fall of blood pressure to 120 systolic, 60 diastolic, and although the patient had a little unusual bleeding, she withstood the operation well. The pathological diagnosis on the uterus was leiomyomas of the uterus and chronic endocervicitis with endocervical polyp. On the

*On leave of absence.

second postoperative day the temperature rose to 101°F. She had considerable nausea and belching, without any vomiting. She was given intravenous fluids for two days and 2 gm. of sulfadiazine daily for nine days. The nausea and belching persisted, and the temperature remained at about 100°F. She had some fullness and a questionable mass in the left lower quadrant. On the tenth postoperative day the hemoglobin was 10.7 gm. per 100 cc. An x-ray film of the chest showed no change from the previous examination. On the twelfth hospital day she was propped up and felt very weak and dizzy. She was still quite nauseated and belched a great deal. She began to complain of anorexia and of distress in the left upper quadrant. Examination of the blood on the seventeenth hospital day revealed a red-cell count of 2,180,000, with 6.6 gm. of hemoglobin, and a white-cell count of 11,400, with 71 per cent neutrophils. In the course of the next two days she vomited coffee-grounds material, which was strongly guaiac positive. The prothrombin time was 22 seconds (normal, 22 seconds). She was given several transfusions. The vomiting subsided, and the red-cell count was 2,500,000, with 7.1 gm. of hemoglobin.

A gastrointestinal series on the twenty-second postoperative day showed a hiatus hernia that measured about 9 cm. in diameter (Fig. 1). The mucosa in the hernia and in the adjoining subdiaphragmatic part of the stomach appeared somewhat widened, but no ulcerations were seen. The hernia was observed to change in size and shape. The remainder of the stomach and the duodenum were normal. There was a laminated, calcified gallstone 8 mm. in diameter in the region of the gall bladder. Following the gastrointestinal series, she had several massive gastrointestinal hemorrhages with bright-red blood in the stools and in the vomitus. She was given nineteen transfusions each consisting of 500 cc. of whole blood, and large amounts of intravenous fluids. She continued to bleed, however, and died on the twenty-ninth postoperative day.

DIFFERENTIAL DIAGNOSIS

DR. ARLIE V. BOCK: It would be interesting to know what the blood findings were. Was the hemoglobin done at the time of the first blood examination?

DR. BENJAMIN CASTLEMAN: It is not recorded.

DR. BOCK: I should like to know whether any stools were examined to indicate whether she was losing blood.

DR. CASTLEMAN: If so, they are not recorded.

DR. BOCK: To go over this briefly, I should say that, in view of the subsequent events, the pelvic condition and the operative procedure probably had nothing to do with the major underlying cause of death. She had a long history of tuberculosis. I

presume that diagnosis is correct in view of the time she was observed in a hospital. The fact that after some twenty years of good health she had a recurrence of the tuberculosis, as indicated by the pulmonary hemorrhage and presumably other signs that are not mentioned, and the fact that she had a nephrectomy, presumably indicate that the diagnosis of tuberculosis had been carefully gone into before the latter step was taken. So I think we can

is usually quite silent. A gastrointestinal disorder with such a hernia usually is infrequent, but when it does occur is characteristic, with a story of difficulty with swallowing or trouble when in the upright position, often relieved by lying down. If the patient bends over, especially to the left, there may be a sensation of something being squeezed up into the chest. There are usually odd sensations of that kind, none of which were present in this case.

FIGURE 1. Roentgenogram Showing the Hiatus Hernia

dismiss the problem of tuberculosis in this case. Some amyloidosis might be found, but I do not believe it could be extensive in this well-nourished woman, and I do not know that it could have had anything to do with hemorrhage anyway.

What are the causes of this type of extraordinary hemorrhage, so severe as to cause death and coming on following the operative procedure that I said I doubted had anything to do with the underlying trouble? The first and obvious thing is the description of the hiatus hernia. The history of bleeding given here, if it has anything to do with hiatus hernia, is decidedly atypical. We know that the usual type of bleeding is oozing for weeks or months, with the development of a secondary anemia, and then subsiding, with gradual recovery from the anemia. Then a secondary period of oozing starts and secondary anemia again develops. The history

The indigestion that is mentioned may very well have been due to the presence of cholecystitis and stone

May I see the x-ray films?

DR. MILFORD SCHULZ: These films merely demonstrate what has already been said in the protocol. Here we have the large hiatus hernia, an unusually large one; apparently it is not paracosophageal, from what can be seen here. There is no evidence of a lesion elsewhere in the stomach or duodenum.

DR. BOCK: In this hospital we have seen many cases of hernia of the stomach much larger than this one.

I should have supposed that if the bleeding in this case were due to hernia, there would have been more history of indigestion, more suggestion of secondary gastritis and much more history of bleeding with a resultant anemia, which would have announced it-

self to the patient by fatigue, palpitation and all the things that go with such an anemia. In view of the fact that the history is silent with reference to this hernia, I am inclined to rule it out as the cause of the bleeding. It is certain that some of these patients have massive hemorrhages and even bleed to death. I suppose that the mechanism of such bleeding is increased venous pressure in the part of the stomach above the diaphragm. There are no ulcerations of the mucosa that bleed. At post-mortem examination this part of the stomach is quite red from congestion, and the part below the stricture pale and normal. But in the present case, with this type of massive bleeding and a silent history, I doubt that the bleeding came from the hiatus hernia.

The next thing that one should consider is the presence of a peptic ulcer. If one rules out hiatus hernia and associated gastritis as the cause of bleeding, then ulcer is the next commonest cause of this type of bleeding, but there is nothing in the history to suggest it. That may not be important, since hemorrhage is often the first sign of ulcer in many cases. I am also influenced by the fact that the duodenal cap is described as normal. Hence, I am inclined to rule out ulcer.

Another possibility is cirrhosis of the liver. There is no history to suggest it; but, again, massive hemorrhage may be the first presenting symptom of cirrhosis of the liver. On the evidence we have here, I cannot rule it out.

Was the serum protein done?

DR. GORDON DONALDSON: No.

DR. BOCK: The dye retention test?

DR. DONALDSON: No.

DR. BOCK: We have no evidence either clinically or from the laboratory data to confirm the diagnosis of cirrhosis, and yet I think it cannot be ruled out and I have to consider it seriously as a cause of this woman's death, with bleeding from esophageal varices.

Did she have a nonvisualized leiomyoma of the stomach? We have made mistakes in the past, when we found nothing by x-ray examination, in assuming that bleeding of an extensive sort in the gastrointestinal tract was due to the presence of an unvisualized ulcer. That is a serious mistake, and because leiomyoma may be present, we should not be satisfied to treat a patient who is bleeding and has had bleeding on a number of occasions by assuming that the diagnosis is one of peptic ulcer. A leiomyoma may be responsible for severe hemorrhage and may cause repeated hemorrhages before anything positive is found by x-ray examination. We have nothing here to support such a diagnosis except the history of hemorrhage.

Judging from the cases of hiatus hernia that I have seen I am inclined to rule this lesion out as the cause of bleeding. I do not believe that the patient had an ulcer. I think that the diagnosis is cirrhosis of the liver or, less likely, leiomyoma. Amyloid disease

may have been found. Without a gastroscopic examination, there is nothing to help in the diagnosis of gastritis.

DR. LELAND S. MCKITTRICK: Does the bright blood that she passed by rectum bother you at all, Dr. Bock, in accepting a lesion of the stomach or esophagus as the source of the bleeding?

DR. BOCK: It does not say how much, but I believe the hemorrhage was considerable and came very rapidly; I still think it was a high hemorrhage.

DR. DONALDSON: Preoperatively, we directed all our efforts toward ruling out tuberculosis as a contraindication to doing anything to the prolapse. The chest and kidney situation was evaluated, and I must say that it was not until after she had bled postoperatively that we got a story of indigestion. She said she had had indigestion only when she was in the tuberculosis sanitarium. On bed rest, she developed indigestion, but never had any nausea or vomiting. We did not discover that she was bleeding until the eighth postoperative day, when we propped her up and found that she was dizzy. She was a fat and sallow woman, and we did not appreciate that she was anemic. On rechecking, we found that the hemoglobin level was surprisingly low, several stools were guaiac positive. We perhaps made a mistake in doing the gastrointestinal series, because following that she bled profusely.

DR. MCKITTRICK: Dr. Donaldson asked me to see this patient in Dr. Arthur W. Allen's absence. She presented quite a problem. Concerning the x-ray examination that Dr. Donaldson tends to doubt his judgment on, I should like to take issue with him on that point, because I think that he was right. It is important to know from where a patient is bleeding, particularly if there is a question of operation. If a definite ulcer could have been demonstrated, this woman would have been operated on with a reasonable chance of surviving the operation. The absence of a demonstrable ulcer, which, as Dr. Bock has said, does not exclude it, makes it less likely and possibly changes the method of approach. So I feel that an x-ray is worth the risk that it may incur in unexplained gastroduodenal bleeding.

Of course the problem was to control the bleeding. The patient had bled massively, or at least she lost a lot of blood. It came from the gastroduodenal region. We thought that it probably did not come from a duodenal ulcer. The bleeding was more massive than that which occurs from hiatus hernia; but knowing that massive bleeding occasionally does arise from that source, we thought that that was probably the answer and we treated her on that basis.

I felt much disturbed about this patient, and I thought that I had let down both Dr. Donaldson and Dr. Allen in not having advised operation. There was one thing in the history that I should have paid more attention to. When a patient bleeds

massively as this patient did we have a right on a nical basis to assume that the bleeding is coming from a large artery. It would be unusual for a diffuse process such as one ordinarily associates with a hiatus hernia to bleed a patient out as promptly as this patient did bleed out. That is rather characteristic of bleeding from a large single vessel, such as occurs in a posterior duodenal ulcer. Therefore, it seemed to me, after this patient had got to the point where we could not operate on her, that I had "missed the boat," in that she probably had a fairly extensive ulceration of a vessel that might have been amenable to surgical attack. By the time I had convinced myself that that might have been the answer, it was too late to do anything about it. She was not a good operative risk. If we had operated, and if she had nothing that we could get at directly, she probably would never have got off the table.

Dr. BOCK: I think that Dr. McKittrick's reasoning is good, but a patient can have massive hemorrhage and bleed to death from hiatus hernia with secondary gastritis. Ordinarily one finds oozing blood from this lesion, with repeatedly positive stools; the patient usually recovers, even though nothing is done about it.

Dr. McKITTRICK: If I had known of patients dying under the circumstances that you describe, I should probably have felt differently than I did

Dr. BOCK: I think that you are correct. I* first became interested in this problem in 1928, when my first case was explored because I could not believe that the bleeding was due to hiatus hernia. The second case had already been explored by the late

FIGURE 3 Drawing of the Interior of the Herniated Portion of the Stomach Showing the Large Ulcer with the Bleeding Fessel.

FIGURE 2 Drawing of the Hiatus Hernia in Situ.

In the law of chance, a rapid depletion must be more frequent from a single vessel than from the type of thing that you are talking about, and sometimes one has to gamble on what is likeliest.

Dr. Daniel F. Jones, who would not believe that the bleeding was due to a hiatus hernia, but we later proved that such was the case.

Dr. CASTLEMAN: But ordinarily one finds that the bleeding has occurred over a long period of time?

Dr. BOCK: Yes; and usually there is a silent history. I cannot believe that this patient bled from the hiatus hernia.

CLINICAL DIAGNOSES

Hiatus hernia.

Gastritis, with massive hemorrhage.

Dr. BOCK's DIAGNOSES

Cirrhosis of liver, with bleeding from esophageal varices?

Leiomyoma of stomach?

Old pulmonary tuberculosis.

ANATOMICAL DIAGNOSES

Diaphragmatic hiatus hernia, with bleeding from ulcer of herniated portion of stomach.

Operation: vaginal hysterectomy and repair, recent; right nephrectomy, old.

Pulmonary tuberculosis, bilateral, inactive.

*Bock, A. V., Dulin, J. W., and Brooke, P. A. Diaphragmatic hernia and secondary anemia, ten cases. *New Eng. J. Med.* 209:615-623, 1913.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The autopsy showed a definite hiatus hernia (Fig. 2). The hernial sac was made up only of pleura and peritoneum, there being no diaphragmatic muscle in that region. The portion of the stomach that was present within the hernia contained a shallow ulcer measuring 4 by 3 cm. (Fig. 3). In its center was an eroded artery, which was the source of the bleeding. We were able to follow that artery back to the gastric artery, which arose from the celiac axis. Microscopic study of the ulcer showed that it did not have the fibrinoid base of a peptic ulcer, but that it was simply necrosis of the mucosa and muscularis mucosa, with a granulation-tissue base. Although the portion of the stomach within the hernia was easily reduced at autopsy, it must have been partially constricted for some time. There was a moderately severe gastritis around the ulcer.

DR. MCKITTRICK: Do you think that the lesion could have been recognized at exploration?

DR. CASTLEMAN: I believe that the hernia could have been reduced at operation, following which you certainly would have been able to feel the ulcer and probably the pulsating bleeding vessel, such as you do in dealing with a posterior duodenal ulcer.

CASE 30172

PRESENTATION OF CASE

A twenty-three-year-old man was admitted to the hospital because of rectal bleeding.

The patient was in excellent health until about twenty months before admission, when he had severe diarrhea lasting four or five days and consisting of ten or more stools a day. There was intermittent, crampy, generalized abdominal pain, especially on the right. The diarrhea subsided except for two episodes, each lasting for one week and occurring three and ten months after the first attack. The crampy pain was present before, during and after the attacks. Ten months before admission he enlisted in the Army, where he underwent basic training for two months. He then had another attack of crampy, low abdominal pain and diarrhea, for which he was hospitalized. With a bland diet the diarrhea subsided but the pain persisted. A gastrointestinal series and Graham test were negative. A barium enema showed a constricting lesion of the right colon. X-ray films of the chest, examination of the sputum and gastric washings for tubercle bacilli and a tuberculin test were negative. Operation was advised, but he requested, and was granted, medical discharge. Following discharge his condition remained the same. One week before admission he had a small gush of bright-red blood following an otherwise normal bowel movement. He

had had no chills, fever, nausea, vomiting, night sweats, loss of appetite or change in weight. No other gastrointestinal or genitourinary symptoms were noted.

Physical examination showed a well-developed, well-nourished man in no distress. The heart and lungs were normal. An abdominal mass was palpated on the right side by one or two examiners. There was no tenderness or spasm.

The blood pressure was 110 systolic, 78 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood showed a red-cell count of 5,760,000, with 86 per cent hemoglobin. The white-cell count was 12,500. The urine was normal.

FIGURE 1. Roentgenogram following Postevacuation Barium Enema.

A blood Hinton test was negative. The stools were dark brown, with a ++++ guaiac test. The non-protein nitrogen was 27.5 mg. per 100 cc., the protein 6.9 gm. per 100 cc., and the chloride 102 milliequiv. per liter. A proctoscopic examination showed a normal rectum.

A plain film of the abdomen revealed gas in the ascending and transverse colon and a small amount of gas and feces in the descending colon, but no gas in the rectum. An intravenous pyelogram was negative. A barium enema showed ready filling of the descending and transverse colon up to the hepatic flexure, at which point the bowel was markedly narrowed for 10 cm. (Fig. 1). Proximal to this, the

cecum did not fill easily. The wall was irregular, but without any change in the mucosal pattern except for shelf formation and small ulcerations. The chest films were negative. A Miller-Abbott tube was passed into the small intestine.

On the tenth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. CHARLES G. MIXTER: I think that, at once, one comes to the conclusion from the history of crampy, generalized, abdominal pain, the change in his bowel function, the blood by rectum, and the presence of a probable mass in the right side of the abdomen, as well as the x-ray findings, that we are dealing with a gastrointestinal lesion probably of the large intestine, but possibly of the small intestine.

May we see the x-ray films?

DR. LAURENCE L. ROBBINS: This is the lesion, approximately 8 cm. in length, in the ascending colon extending nearly to the hepatic flexure. The lumen appears to be narrowed to about 2 or 3 mm. in diameter—perhaps 5 mm. at its widest portion. I do not believe that one can be absolutely sure of ulceration, but certainly the possibility is suggested. One thing that does appear to me more significant than is expressed in the report is that the margins are not typically "shelf-like" and seem to change the least bit in the various films. There is absence of the normal mucosal pattern. The chest is negative.

DR. MIXTER: That does not correspond with the usual spool-like type that one would associate with cancer of an obstructive nature.

DR. ROBBINS: Not typically.

DR. MIXTER: From these findings we can rule out the other systems, and limit our consideration to the intestinal tract.

As I read this over, there came to mind, of course, the different lesions that I associate readily with three of the factors here—namely, the probable mass, the presence of blood, substantiated by one episode of bright-red bleeding and the + + + + guaiac test, and the x-ray findings. I can remember years ago as an intern here, when Dr. Maurice Richardson would see a case with an obscure diagnosis, he would always say, "Well, I will take the appendix against the field." One always does have to consider the possibility of chronic appendiceal abscess, but I think we can rule it out on account of the duration of the story, the lack of emaciation, the lack of fever and the lack of the typical onset with the attack, and perhaps the presence of diarrhea.

Actinomycosis perhaps would come to mind from the presence of a mass, but again, if the story is as long as the protocol tells us, one would expect the patient to have a frank abscess by this time. Furthermore, in my experience, blood is not

a feature in dealing with actinomycosis of the cecum.

Sarcomatous lesions, of course, are more frequent in the small than in the large bowel, and the pressure defect is lateral in type, not the annular type that these x-ray films suggest. The patient could have had bleeding from ulceration, but he was in good physical condition, had a surprisingly good red-cell count, and his white-cell count was only slightly elevated. I think that we can rule out sarcomatous lesions, particularly the lymphoblastic group.

Occasionally one sees a rare case of simple ulceration of the colon. We have had two or three such cases in our clinic at the Beth Israel Hospital. They are generally seen in the older age group, patients who are around fifty or more, and are characterized by bleeding, and by the presence of an ulcer, generally of good size, picked up by x-ray examination. What the etiology is, I do not know. We have not seen them in the perforated stage. Here we find a definitely long, tubular, constricting lesion, so we can rule out simple ulceration of the colon.

Diverticulitis, of course, will cause a constriction and a mass. Diverticulitis is a disease of the old-age group. It is usually, however, not characterized by bleeding. It is almost invariably multiple, and it is much more prone to involve the left colon than the right. The chances are, from all these facts, that we can discard that as a possibility.

Ileocecal tuberculosis is a possibility. Here, in the East, where the majority of milk is pasteurized, the surgical tuberculous lesions of childhood are rare. They have disappeared remarkably in the last thirty years or so. Another large entity that was frequently placed in the group of ileocecal tuberculosis has been removed from that category by the recognition of regional enteritis, or terminal ileitis. Ileocecal tuberculosis, however, unquestionably occurs. Sometimes tubercle bacilli can be picked up in the stools. In the last case that I personally encountered, there was marked involvement of the appendix, which resembled a good-sized yellow banana. That patient had tubercle bacilli that were readily identified in the stool. Usually, of course, there are accompanying signs—evidence of calcareous nodes elsewhere in the abdomen or signs in the chest. It is frequently accompanied by quite severe bleeding and usually by tenesmus. This man was in good physical condition and had no anemia, and I should say that his general condition did not fit the picture of ileocecal tuberculosis.

The patient was twenty-three years old, and because of that, at first glance, one rules out cancer of the ascending colon. Of course that does not always hold. We have had four or five cases of intestinal neoplasm in the twenty-year-old group. One boy that we had a couple of years ago came in with a mass and had a distinct family history of carcinoma, and his father had died less than five years before of carcinoma of the rectum. He had ear-

NEW HAMPSHIRE MEDICAL SOCIETY

DEATH

COBURN — Clarence O. Coburn, M.D., of Candia, died March 30. He was in his sixty-second year.

Dr. Coburn, son of William P. and Sarah (Hubbard) Coburn, was born in Manchester and graduated from Tufts College Medical School in 1906. He was vice-president of the Manchester Rotary Club, a trustee for several years of the Currier Gallery of Arts, president of the Medical Staff at the Elliott Hospital and a member of the Manchester, Hillsborough County and New Hampshire medical societies. He served as president of the New Hampshire Medical Society in 1939.

He is survived by his widow, two daughters, one son, four brothers and one sister.

Luncheon for the alumni, as guests of the trustees, will be held in the House Officers' Dining Room at 12:30 o'clock.

WASHINGTONIAN HOSPITAL

Mr. Reuben L. Lurie, chairman of the Parole Board, Massachusetts Department of Correction, will give the final lecture in the series on alcoholism, being held under the cosponsorship of the Washingtonian Hospital and the Committee on Alcoholism of the Boston Council of Social Agencies on Friday evening, May 12, at 7:30, at Zero Marlborough Street, Boston. His topic will be "Alcoholism, Criminology and Parole." Mr. Elwood H. Hettrick, dean of the Boston University Law School and a member of the Board of Directors of the hospital will preside.

NEW ENGLAND HOSPITAL
FOR WOMEN AND CHILDREN

The monthly clinical conference and meeting of the staff of the New England Hospital for Women and Children will be held on Thursday, May 4, in the classroom of the Nurses Residence at 7:15 p.m. Dr. Susannah Friedman will present and discuss the following two cases from the Urological Department: "Multiple Bilateral Renal and Ureteral Calculi and Their Removal" and "Bladder Papillomas — Late Complications."

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING
THURSDAY, MAY 4

THURSDAY, MAY 4

*9:00-10:00 a.m. Medical clinic. Dr. S. J. Thannhauser. Joseph H. Pratt Diagnostic Hospital.

7:15 p.m. New England Hospital for Women and Children. Monthly clinical conference and meeting of the staff.

FRIDAY, MAY 5

*9:00-10:00 a.m. Errors in Cardiovascular Diagnosis. Dr. Paul D. White. Joseph H. Pratt Diagnostic Hospital.

*12:00 m. Massachusetts Central Health Council. The Pioneer, Y. W. C. A., 140 Clarendon Street, Boston.

SATURDAY, MAY 6

*9:00-10:00 a.m. Medical clinic. Dr. William Dameshek. Joseph H. Pratt Diagnostic Hospital.

12:30 p.m. Boston City Hospital Alumni Association. Cheever Amphitheater, Dowling Building.

*10:00-11:30 a.m. Medical staff rounds. Peter Bent Brigham Hospital.

MONDAY, MAY 8

*9:00-10:00 a.m. Medical clinic. Dr. Samuel Proger. Joseph H. Pratt Diagnostic Hospital.

*12:15-1:15 p.m. Clinicopathological conference. Peter Bent Brigham Hospital.

TUESDAY, MAY 9

*9:00-10:00 a.m. Medical clinic. Dr. S. J. Thannhauser. Joseph H. Pratt Diagnostic Hospital.

*12:15-1:15 p.m. Clinicoröntgenological conference. Peter Bent Brigham Hospital.

WEDNESDAY, MAY 10

*9:00-10:00 a.m. Electric Shock Treatment. Dr. Abraham Myerson. Joseph H. Pratt Diagnostic Hospital. New England Oto-Laryngological Society. Spring meeting. Massachusetts Eye and Ear Infirmary.

*12:00 m. Clinicopathological conference. Children's Hospital.

*Open to the medical profession.

ALLOXAN DIABETES WITH DIABETIC COMPLICATIONS*

C. CABELL BAILEY, M.D.,† ORVILLE T. BAILEY, M.D.,‡ AND RACHEL S. LEECH, A.B.§

BOSTON

THE production of fatal hypoglycemia² in rabbits by the intravenous administration of alloxan⁴ (the ureide of mesoxalic acid) was described in 1937 by Jacobs.¹ Grossly, the organs of these rabbits appeared normal. No histologic studies were described. In 1943, Dunn, Sheehan and McLetchie^{2, 3} made similar physiologic observations and, in addition, pointed out that there was coincident selective necrosis of the islets of Langerhans without injury to the acinar tissue of the pancreas. Bailey and Bailey⁴ confirmed both the physiologic and the histologic findings of Jacobs and of Dunn, Sheehan and McLetchie. They further found with rabbits that if death in hypoglycemia is prevented by the administration of intravenous dextrose, permanent diabetes mellitus develops within twenty-four hours. Brunschwig, Allen, Goldner and Gomori⁵ demonstrated transitory hyperglycemia after the intravenous administration of alloxan in rabbits and produced sustained hyperglycemia in 5 dogs. Later Goldner and Gomori⁶ described in detail the production of alloxan diabetes in dogs. They also injected alloxan into 3 human patients with carcinomatosis. One of the carcinomas arose in the islets of Langerhans. They found no change either in the blood-sugar levels or in the clinical condition of any of the patients. In later papers, Dunn, Kirkpatrick, McLetchie and Telfer⁷ and Dunn and McLetchie⁸ discussed their experiments on rabbits in detail and recorded the production of sustained hyperglycemia in 5 of 8 albino rats injected with alloxan. A more complete summary of the literature appears in the recent progress article by Joslin,⁹ which, however, does not include a paper by Hard and Carr¹⁰ who report the effect on rabbits of doses of alloxan of various sizes.

The purpose of this paper is to describe the occurrence of diabetic cataracts in rabbits made permanently diabetic by the use of alloxan, to discuss the effect of repeated small doses of alloxan in rabbits, as well as the lesions in the islets of Langerhans of rabbits immediately after the production of alloxan diabetes, and to describe a simple method for the production of alloxan diabetes in the rat, with the development of cataracts in two animals and of diabetic coma in another.

DIABETIC CATARACTS IN RABBITS

Cataracts developed in 5 rabbits made diabetic by the intravenous administration of 200 mg. of alloxan per kilogram of body weight, as previously recorded.⁴ In each the cataract developed between four and six weeks after the diabetes was induced. All the rabbits had severe diabetes and were kept alive and in good condition from two and a half to five and a half months with the injection of 12½ to 8 units of insulin daily.

The development of the cataracts has been followed by Dr. William Beetham, who reports that lens opacities are easily seen with oblique illumination and the ophthalmoscope. These changes are chiefly subcapsular, and are now more advanced in the posterior cortex, where they seem to appear earlier than in the anterior cortex. There is no definite arrangement of the opacities, although a rosette-shaped design in the posterior cortex has been noted in several animals and in some others the opacities are nearer the lens equator, forming a ring, with the pole of the lens relatively clear. Marked vacuole formation and irregular water clefts are seen with the ophthalmoscope. The slit-lamp (magnification 40x) also shows diffuse cloudiness of the cortical layers and, in a few rabbits, many highly refractile and iridescent crystals resembling the cholesterol crystals seen in human lenses were observed. The changes may progress rapidly, the fundus oculi being visible at one examination and invisible three weeks later. In the rabbit having diabetes for the longest period, five months, the

cataracts have reached sufficient density to prevent visualization of the details of the fundus.

EFFECT OF REPEATED SMALL DOSES OF ALLOXAN IN RABBITS

Complete histologic studies made on several alloxan-diabetic rabbits revealed that the tissue changes related to the administration of alloxan were confined to necrosis of the islets of Langerhans, mild tubular degeneration of the kidneys and slight fatty metamorphosis of the liver. There were no morphologic changes in any of the endocrine glands other than in the islets of Langerhans. The histologic findings in alloxan diabetes offer further direct evidence that lesions of the islets of Langerhans are sufficient to produce the physiologic changes of diabetes mellitus. Thus, an experimental method is now available for the production of pancreatic diabetes without loss of the external secretion of the pancreas.

It seemed important to investigate the effects of repeated small injections of alloxan, to see whether these would have a cumulative effect and, if so, whether a permanent or a transient diabetes would result. To test these possibilities, 8 rabbits were given small repeated intravenous injections of alloxan.

Three rabbits were given 20 mg. of alloxan per kilogram of body weight intravenously three times a week for two months, and their blood sugars, twenty-four-hour urine samples and general condition were carefully followed. None developed hyperglycemia, glycosuria or any sign of diabetes.

Another 3 rabbits were given 40 mg. of alloxan per kilogram in repeated intravenous injections. Two of these had daily injections and developed diabetes after the seventh and thirteenth injections respectively. After two blood-sugar levels over 200 mg. per 100 cc. had been obtained, with concomitant glycosuria, both rabbits were sacrificed for pathological study. In the pancreases, there were striking changes in the islets of Langerhans. The cells of each islet showed a variety of lesions. Some cells, especially those at the periphery of the islets, appeared essentially normal. In other cells, the nuclei were well preserved, as was the ground substance of the cytoplasm, but the granules were not present. Numerous cells presented a clear-cut picture of hydropic degeneration, which has been shown to be a reversible change.¹¹⁻¹⁵ Among the cells with hydropic degeneration there were occasional ones with large, clear vacuoles but with the nuclei staining in a homogeneous manner and without chromatic pattern. This appears to be an irreversible change because of the nuclear damage. Mitoses were seen in several islet cells, but in no case was there more than one mitosis in an islet (Fig. 1). This complex picture of normal cells, slightly injured cells, cells with hydropic degeneration, irreversibly damaged cells and a mitosis in a

single islet is not clearly duplicated in any other form of experimental diabetes or in human patients. It seems best interpreted as a complex response to an injurious agent, with some cells capable of survival if the agent is removed, whereas others are dead and are being replaced by mitotic division of surviving islet cells.

In the third rabbit receiving 40 mg. of alloxan per kilogram three times a week, diabetes appeared after the tenth injection, with the blood-sugar level reaching 332 mg. On cessation of the injections, the diabetes seemed to disappear. Subsequent and careful observation over two and a half months, however, shows that mild diabetes persists, with occasional blood-sugar levels as high as 228 mg.

The seventh rabbit received successive doses of alloxan amounting to 20, 40, 60 and 60 mg. per kilogram, with two-day intervals between the first three injections and a ten-day interval between the third and fourth. Following the last injection, permanent severe diabetes appeared, with the blood-sugar level reaching 490 mg. and with 6.4 per cent glycosuria. This rabbit has remained diabetic for five and a half months and still requires 2½ units of crystalline insulin daily.

The eighth rabbit received 20 mg. of alloxan per kilogram three times a week for seven, one-day intervals. After the fourth injection, hyperglycemia appeared for one day, with blood-sugar levels of 272 and 300 mg. Despite continued injections, the diabetes had disappeared by the next day and did not recur during the next two and a half months of careful observation. This transitory diabetes has not appeared in another animal, although in one, reported above, the diabetes became much milder after the injections were discontinued.

It appears that repeated doses of 20 mg. per kilogram were not sufficient for the production of diabetes. This was the case even though the total amount of alloxan injected was extremely large, one rabbit receiving a total of 580 mg. per kilogram. Doses of 40 mg. per kilogram, on the other hand, regularly produced diabetes in all rabbits in which they were tried. In these animals, a single dose had no effect, as shown by repeated determinations of the blood-sugar level on the day of injection. In those rabbits that developed diabetes, however, the morning blood-sugar level tended to rise a little each day until diabetes finally appeared.

These results suggest a cumulative effect of alloxan, and further indicate that repeated doses of 40 mg. per kilogram or larger are necessary to produce sufficient accumulation to influence the islets of Langerhans. The hydropic degeneration found immediately after the development of diabetes^{11, 12} suggests that, as pointed out by Allen,¹³ Lukens and Dohan,¹⁴ and Copp and Barclay,¹⁵ who studied other animals in experimental diabetes produced by partial depancreatotomy or by crude anterior-pituitary extracts, the injury in these particular cells is

reversible rather than permanent. Such changes have been reported in early cases of human diabetes.¹⁶⁻¹⁸

ALLOXAN DIABETES IN RATS

The effects of alloxan on rats have recently been studied. Fifteen rats were made diabetic in this way. The intraperitoneal and intravenous routes of administration did not prove satisfactory. Of 6 rats injected intraperitoneally with from 200 to 400 mg.

Diabetic cataracts developed in 2 rats made diabetic with alloxan and kept alive for four months. In one of these, cataracts have completely obstructed all vision.

Diabetic acidosis developed in 1 rat. This animal, which weighed 149 gm., received 200 mg. of alloxan per kilogram subcutaneously. Forty-eight hours later, marked polyuria and polydipsia were apparent and the blood-sugar level was 820 mg. The rat

FIGURE 1. An Island of Langerhans from the Pancreas of a Diabetic Rabbit.

This rabbit had been given seven intravenous injections of alloxan, each of 40 mg. per kilogram of body weight. Some of the cells are essentially normal; many show hydropic degeneration, a few are dead; and one is in mitosis. (Camera lucida drawing at $\times 1100$.)

of alloxan per kilogram, only 1 developed diabetes. Three died with extensive liver necroses, and 2 remained alive and well. Subcutaneous Nembital was necessary to alleviate the pain, which lasted for several hours after this injection. At autopsy, considerable inflammatory reaction was found on the peritoneum. Four rats were injected intravenously with 150 to 300 mg. of alloxan per kilogram. All died within two days.

The subcutaneous route of administration was used in 26 rats, with dosages varying from 100 to 300 mg. per kilogram. Fourteen of these developed diabetes, 4 died, and 8 have continued alive and well. Two hundred milligrams of alloxan per kilogram proved to be the most feasible dose, since 12 of the 15 rats receiving this dose developed diabetes.

appeared sick. On the third day, acetone appeared in the urine and the animal lay on its side, apparently moribund. It received 0.2 units of insulin, which was repeated in two hours. Marked improvement supervened, and by the fifth day the animal appeared alert and well on a maintenance dose of 0.5 units of crystalline insulin daily. Observations on diabetic acidosis induced by alloxan in rabbits have already been reported from this laboratory.⁴

One rat also developed diabetic coma, which is a further indication that the diabetes induced by alloxan in rats is severer than that produced by pancreatectomy. This animal received 200 mg. of alloxan per kilogram subcutaneously. By the third day, polydipsia and polyuria were evident. On the fourth day the blood-sugar level was 720 mg., aceto-

nuria was marked, and the rat developed typical diabetic coma with extreme polydipsia, dry tongue, Kussmaul respiration and drowsiness, leading eventually to unconsciousness and death that evening.

The histologic findings in this case were of considerable interest. In the pancreas, the islets of Langerhans were destroyed. Except for one islet, there were no traces of islet cells of any type, and the original sites of the islets could be found only after search. The acini were essentially normal in appearance. In contrast to the findings in rabbits, but in conformity with those in other rats, there was a diffuse infiltration of the interstitial tissue with mononuclear cells and polymorphonuclear leukocytes. These were scattered uniformly throughout the stroma of the pancreas; no concentration was found about the ducts or in the sites formerly occupied by the islets of Langerhans. In the liver there was congestion of the sinusoids of the central portions of lobules. No necroses were present. Many of the liver-cord cells contained small fat droplets. One adrenal gland contained a small area of necrosis in the cortex, with infiltration by polymorphonuclear leukocytes. Similar lesions have been encountered in control rats, for which reason this finding is not regarded as significant. The other adrenal gland was normal. There was conspicuous tubular degeneration in the kidney. The proximal convoluted tubules were swollen, and small vacuoles were present in the basal portions of many cells. The epithelium of the distal convoluted tubules was shrunken in some places. These tubules and also the collecting tubules contained eosinophilic material, which appeared granular. No changes were noted in the interstitial tissue, and no polymorphonuclear leukocytes were seen. The blood vessels of the kidney, as well as those of other organs, were normal. The degree of renal damage was far greater than that in any of the rabbits examined. Study of other organs failed to reveal any deviations from the normal. All 6 rats studied histologically showed selective necrosis of the islets of Langerhans. Unlike the rabbits, however, the 5 rats that received the drug intraperitoneally or intravenously showed extensive necrosis of the liver and extremely severe lesions of the kidney, predominantly tubular in type. The rat described above that received alloxan subcutaneously and developed diabetic coma did not have liver necrosis.

It thus appears that diabetes may be produced by alloxan in rabbits with only slight injury to organs other than the islets of Langerhans. In rats, diabetes may be produced but with considerably greater in-

jury to other organs. When an appropriate dose is administered by the subcutaneous route, however, the changes in the majority of cases are not so severe as to cause death.

SUMMARY

Bilateral diabetic cataracts developed in four to six weeks in rabbits made diabetic with alloxan.

The production of alloxan diabetes in rabbits depends on the dosage. Repeated injections of 20 mg. per kilogram were not sufficient to produce diabetes. Forty-milligram doses produced diabetes within two weeks in 2 rabbits, suggesting a cumulative effect of alloxan with the larger dose.

Histologic studies of the pancreas in 2 rabbits immediately after the production of diabetes by the repeated injection of 40 mg. of alloxan per kilogram revealed that some cells of the islets of Langerhans showed hydropic degeneration, others showed irreversible changes, and some were essentially normal, whereas occasional cells were in the process of mitotic division. The pancreatic acini were normal.

In rats, the subcutaneous administration of 200 mg. of alloxan per kilogram is feasible for producing diabetes.

The occurrence of cataracts and of diabetic acidosis and coma in the rat is reported.

Mrs. Leech and Miss Hazel Hunt supervised the chemical analyses made in this study. They and Miss Barbara Jacob gave valuable technical assistance.

INFECTIONS ASSOCIATED WITH AN EPIDEMIC OF PRIMARY INTERSTITIAL PNEUMONIA*

CUTTING B. FAVOUR, M.D.†

BOSTON

IN 1935, Bowen¹ reported the occurrence of pneumonia in 5 to 25 per cent of cases of so-called "flu" in which routine roentgenograms of the chest were taken. Since that report, clinical attention has been focused particularly on cases of respiratory infection with roentgenologic evidence of primary interstitial pneumonia; little information has been accumulated regarding the minor related respiratory infections. In 1940, however, Reimann and Havens² reopened the latter phase of the subject with the report of an epidemic in which 88 per cent of the patients were ill with nasopharyngolaryngitis, 6 per cent had in addition tracheobronchitis and 6 per cent had tracheobronchopneumonia. Dyer and his co-workers³ did not find so great an association of minor illness with an outbreak of Q fever. Dingle and others⁴ observed a large number of cases of minor respiratory infections that occurred at the same time as an outbreak of primary interstitial pneumonia at Camp Clairborne, Louisiana, but could find no direct epidemiologic relation between the two groups of cases. Iverson,⁵ reporting an epidemic in a boys' camp, stated that 60 to 80 per cent of approximately 100 persons had respiratory symptoms, 35 per cent were confined to bed with a severe cough and only 6 per cent suffered from primary interstitial pneumonia.

From June, 1942, to February, 1943, inclusive, an intramural epidemic of atypical pneumonia and related respiratory illness occurred among the personnel, numbering approximately 300, of the Peter Bent Brigham Hospital. This afforded an excellent opportunity to study the relation between common upper respiratory infections and the current form of atypical pneumonia. A description of this epidemic and an analysis of its salient features follow.

CLINICAL DATA

First Local Epidemic

On June 13, 1942, Dr. A, developed cough, malaise and fever ranging up to 104°F. On June 14, a roentgenogram of the chest showed an extensive pneumonia. Instead of going to bed, he remained ambulatory in order to attend examinations that took place on June 15, 16 and 17. For the next three weeks he was desperately sick. Violent nonproductive paroxysms of coughing, cyanosis, periodic delirium and bilateral pulmonary mottling (similar

to that of terminal miliary tuberculosis) as shown by x-ray examination characterized his illness. Recovery was delayed for three months.

Between examinations Dr. A, talked outdoors to Drs. B₁, B₂ and B₃, with whom he also rode about in a car. He spent his evenings and nights at home during this period, thus exposing his wife, B₄. B₁ returned to the Brigham Surgical Service, where he worked until admitted as a patient on July 4, seventeen days following his first exposure to A₁, with a severe atypical pneumonia. B₂ returned to the Massachusetts General Hospital Surgical Service, where he too worked until hospitalized on July 4, seventeen days following his first exposure to A₁, with an even more persistent atypical pneumonia. B₃ left for a new position on the medical service of another hospital, where he developed a less acute but equally persistent atypical pneumonia on July 5, eighteen days following his first exposure to A₁. Also on July 5, B₄, eighteen days following her first exposure to A₁, developed severe atypical pneumonia (Table 1).

B₁, who came to the Peter Bent Brigham Hospital, developed his illness in two stages: a prodromal period of five days marked by chilly sensations, low-

B ₃ .. .	16-18
B ₄ .. .	13-18

grade fever, muscle aches and a slight, dry cough; and an acute stage of ten days characterized by high fever (103 to 104°F.), a paroxysmal dry cough, cyanosis, scattered bronchial rales and, as shown by roentgenographic examination, a diffuse mottling of the left lower lobe.

Three student nurses (C₁, C₂ and C₃) and 1 graduate nurse (C₄) who worked with B₁ during his prodromal period became ill, as shown in Table 2. In contrast to C₁, C₂ and C₃, whose oral temperatures did not rise above 100°F., C₄ had fever up to 102°F., the classic cough of atypical pneumonia and increased hilar markings on the left side as shown by x-ray. Two of the nurses (C₁ and C₂) had gastrointestinal upsets.

During the acute stage, B₁ was carefully isolated in a single room on a third-floor ward.† Three stu-

*From the Medical Clinic, Peter Bent Brigham Hospital, and the Department of Medicine, Harvard Medical School.

dent nurses (C_5 , C_6 and C_7) who took care of him became ill, as shown in Table 3.

The gastrointestinal upsets in the two pairs of contacts, C_1 and C_2 and C_5 and C_6 , were unusual in that they did not occur in each pair on the same day, were accompanied by tracheobronchitis or prostration out of proportion to the disturbance in the fluid balance and did not yield enteric pathogens in the cultures of the stools.

The sick nurses were isolated in their rooms in the nurses' home and the single rooms of a previously

A complete list of the hospital personnel who were exposed to him is given in Table 4. Of 10 direct contacts, 7 became sick after a delay of one to fourteen days. The illnesses included 2 cases of pneumonia, 3 of tracheobronchitis and 2 of so-called "colds." The probable incubation period was seven to fourteen days.

X_3 , a houseofficer who developed atypical pneumonia, was isolated on a third-floor single-room ward. A strict isolation technic was observed, with the use of masks, gowns and scrubbing. Contacts

unexposed medical ward. One cross infection seemed to come from the C group, occurring in D_1 , a graduate nurse, who developed moderately severe tracheobronchitis lasting a week twelve days after close contact with her roommate, one of the above group.

Second Local Epidemic

During the first two weeks of August, 1942, a lull in respiratory infections among the hospital personnel occurred, amounting in effect to a natural quarantine period. On August 12, W_1 was admitted to the private pavilion on the eleventh day of a moderately severe atypical pneumonia. Up to three days before his discharge from the hospital on August 24, he had fever and a paroxysmal dry cough.

during the prodromal period before isolation and later during the acute illness are listed in Tables 5 and 6. Of the 15 contacts during the prodromal period, 4 became ill — 3 with tracheobronchitis and 1 with an acute gastrointestinal upset. Of the 12 contacts during the period of acute illness, 7 became ill — 5 with tracheobronchitis (including 3 with an additional gastrointestinal upset), 1 with pneumonia and 1 with a "cold." The probable incubation periods varied from nine to thirteen days. X_9 , a student nurse who developed atypical pneumonia, did not have a prodromal period but became sick abruptly and was isolated in another part of the hospital. Table 7 shows the contacts. Of the 8 contacts, 6 became ill — 3 with tracheobronchitis, 2 with pneumonia and 1 with an acute gastrointestinal up-

set. Both contacts who remained well had been previously exposed to cases of atypical pneumonia.

The proportion of student nurses who became ill as a result of exposure to atypical pneumonia was greater than it was among graduate nurses. In general, visiting physicians, houseofficers and nurses who had been repeatedly exposed to atypical

until November 14. This group survey brought to our attention all persons with fever and most of those with symptoms. On September 28, a sixteen-bed medical ward was set aside for so-called "virus patients." Five days later a thirty-bed ward was substituted for this purpose. There for the next month the daily census of epidemic patients — those with

pneumonia during previous years seemed to be relatively immune to the infection.

Major Epidemic

By September the number of cross infections was becoming too great to follow and isolate individually (Fig. 1). On September 21, the daily taking of temperatures (at 4 p.m.) of all persons working with patients was begun. This regimen was continued

pneumonia, tracheobronchitis, fever of unknown origin and fatigue — was never less than 20.

EPIDEMIC CONSIDERATIONS

During the nine months of this intramural epidemic, there occurred among approximately 300 hospital personnel who had direct contact with patients 231 cases of epidemically related infections (including 29 cases of primary interstitial pneumonia)

and 156 additional illnesses, not related to the epidemic, which were carefully studied for control purposes. These control illnesses are shown in Table 8 and Figure 1.

The epidemic cases occurred in four forms: atypical (primary interstitial) pneumonia, tracheobron-

chitis, a fatigue syndrome and fever of unknown origin. The epidemic cases occurred in four forms: atypical (primary interstitial) pneumonia, tracheobron-

FIGURE 1. Occurrence of Known Disease in 300 Members of the Personnel of the Peter Bent Brigham Hospital (June, 1942, to March, 1943).

One square on the abscissa represents five days. One square on the ordinate represents 1 case whose day of acute onset fell within that five-day period. Of the cases of tracheobronchitis, the solid black squares are single attacks, the diagonal squares are first attacks, the spotted squares are second attacks (an asymptomatic interval of three or more weeks), the P squares are attacks of tracheobronchitis three or more weeks after recovery from atypical pneumonia, and the O squares vice versa. The black, diagonal and spotted squares apply similarly to fevers of unknown origin. Fatigue syndromes are gray only. It is to be noted that the majority of single and first attacks of tracheobronchitis came during the hospital epidemic of atypical pneumonia. On the other hand, the majority of repeat attacks came during the influx of outside cases of atypical pneumonia. The minor illnesses charted at the top apparently did not bear on the epidemic syndromes.

chitis, a fatigue syndrome and fever of unknown origin.

Atypical pneumonia. Among the approximately 300 hospital personnel, 29 persons contracted atypical pneumonia. This was 43 per cent of the total

X-ray Department where 4 of the 9 members, comprising physicians, nurses and technicians, contracted the disease. In addition, the valet of a private patient developed atypical pneumonia thirteen days after a one-day exposure on the virus ward.

Tracheobronchitis. This was the most frequent form of epidemic infection; 164 attacks, or 71 per cent of the 231 epidemic infections, occurred in 111 persons. Seventy were single attacks and 22 were first attacks. Of the former, 4 were followed after three weeks or more of normal health by atypical pneumonia, 1 occurred two months after recovery from atypical pneumonia, and 1 was the first of two widely separated attacks that occurred three months after atypical pneumonia. Most interesting were 11 first attacks that became chronic with repeated exacerbations on re-exposure to virus patients. An example of these is a student nurse who was sent home to convalesce when a period of two weeks off

cases of atypical pneumonia seen in the hospital during the nine months of intensive study. The attack rate was highest among those most directly in contact with other cases of pneumonia and in those most overworked. Atypical pneumonia developed

therapy had proved ineffectual in alleviating her symptoms. Ten days later her father developed pneumonia, which did not respond to a sulfonamide in the local hospital. On returning to work, the nurse continued to cough in characteristic paroxysms. Several periods of one or more weeks of bed rest did not clear the cough or the malaise and fatigability. On two occasions exposure to a patient with acute atypical pneumonia resulted in a return of symptoms. Roentgenograms of the chest and blood studies were repeatedly negative. The cough persisted through the first nine months and over a year later still recurred.

Of the patients with nonchronic tracheobronchitis who had more than one attack, 22 had two attacks and 6 had more than three, all separated by three or more weeks without symptoms. Characteristically, those who suffered multiple attacks had them when most heavily exposed to patients with atypical pneumonia or tracheobronchitis (Fig. 1). In some of those infected for the second time, the specific contact was known and the incubation period was found to be the usual seven to fourteen days.

Other epidemic syndromes. During the epidemic, a fatigue syndrome was observed in 15 patients (Fig. 1). Fever of unknown origin (21 patients with twenty-three attacks), consisting of a low-grade oral temperature of not over 100°F., accompanied the fatigue syndrome during the mass temperature-taking. Occasionally there was a one-day to three-day rise of temperature to 102°F. or more, with acute prostration but without localizing physical signs or abnormal laboratory findings. It was interesting that none of the patients with either of these syndromes contracted cross infections from patients with tracheobronchitis or atypical pneumonia when out on the virus ward for study.

DISCUSSION

The relation between nonpneumonic forms of epidemic or sporadic respiratory infections and atypical pneumonia is the subject of this report. Atypical pneumonia is usually thought of as a nonfatal, relatively noninfectious sporadic infection⁷⁻¹¹ that may occur in epidemics.^{1, 2-6, 12, 14-16} In isolated cases, viruses have been implicated as the etiologic agent, with hens,¹⁵ cats¹⁶ and birds¹⁷ the vectors. Occasionally experimental animals have been infected with human material.¹⁸⁻²⁰ Recently Rose²¹ succeeded in transmitting the disease from patients to young guinea pigs. In other hands the average patient yields no virus and gives no clues regarding where he acquired his illness. For this reason diagnostic criteria have been limited to the actual x-ray demonstration of a pulmonary lesion, the failure of the infection to respond to a sulfonamide, negative bacteriologic studies and eventual recovery.

In the group study at Camp Clairborne, Louisiana, conducted by Dingle and his co-workers,⁴ emphasis

was placed on related nonpneumonic respiratory infections. These workers found that tonsillitis could be separately classified, both symptomatically and by physical signs. A large group of other infections, however, called "bronchitis resembling atypical pneumonia" and "other diseases of the respiratory tract," could be differentiated from atypical pneumonia only by a milder course and by lack of x-ray evidence of pneumonia. Although a common etiologic agent seemed probable, specific epidemiologic or laboratory evidence of cross infection was not found.

In the present study, an epidemiologic relation between atypical pneumonia and related infections was present. On the other hand, the minor illnesses of all the institutional groups comprising sore throats, gastrointestinal upsets and common colds, did not seem to be related to the epidemic, although gastrointestinal symptoms were associated with cough in a few cases in which exposure to patients with atypical pneumonia about two weeks previously strongly suggested that they were suffering from the same infection. The total infections, including both epidemic and minor illnesses, comprised 387 attacks of illness in a population of about 300 people: Two hundred and thirty-one of these attacks (60 per cent) consisted of one or another of the epidemic syndromes. Of the epidemic cases, 12 per cent were atypical pneumonia, 16 per cent were fatigue or fever of unknown origin and 71 per cent were tracheobronchitis. If a person contracted a clinical epidemic infection, he had one chance in eight of having pneumonia, one in six of having fatigue or fever only and three in four of having tracheobronchitis. If a person previously unexposed had had no one of these syndromes, he was extremely likely to be infected as shown by the occurrence of 231 attacks of epidemic illness among approximately 300 people. It is also interesting that a chronic form of tracheobronchitis sometimes occurred.

SUMMARY

Two hundred and thirty-one epidemically related attacks of infection occurring among the personnel of the Peter Bent Brigham Hospital, numbering approximately 300, are reported. Twenty-nine persons had atypical pneumonia, 111 had 164 attacks of tracheobronchitis, 23 had fever of unknown origin and 15 had a fatigue syndrome. One hundred and fifty-six colds, sore throats, gastrointestinal upsets and other infections that occurred during the nine months of the study showed no correlation with the epidemic, although a few patients with atypical pneumonia and tracheobronchitis had gastrointestinal symptoms.

Cases of atypical pneumonia represented 12 per cent and those of tracheobronchitis 71 per cent of the epidemic syndromes.

MEDICAL PROGRESS

HEMATOLOGY (Concluded)

WILLIAM DAMESHEK, M.D.*

BOSTON

HEMORRHAGIC DISEASES

IN GENERAL one may say that there are three mechanisms concerned in the clotting of blood: the blood platelets, the capillary endothelium and certain enzymatic and chemical factors within the blood. A hemorrhagic condition may ensue if any of these mechanisms becomes impaired. Thus, one may classify the hemorrhagic diseases as follows: those concerned with an abnormality of the platelets, those with an abnormality of the capillary wall and those with an abnormality of the circulating clotting factors.

Platelet Abnormalities

The most frequent abnormality of platelets resulting in hemorrhage is great diminution in number. Some authorities claim that petechiae do not develop even in gross platelet deficiency unless the capillaries are simultaneously involved. Although it is true that patients with similarly reduced platelet counts differ in their hemorrhagic tendency, it cannot be denied that it is the low platelet count that initiates the bleeding; furthermore, a capillary defect in acute leukemia, aplastic anemia and so forth has not been established. The so-called "capillary defect" in idiopathic thrombopenic purpura may be more fanciful than real. Platelet diminution occurs when the bone marrow is seriously involved, as in chemical poisonings, leukemias and neoplasms and in severe deficiency states, — when the spleen is enlarged, and idiopathically, — perhaps owing to some unknown splenic mechanism, as in idiopathic thrombopenic purpura. That the sulfonamide drugs

occasionally result in thrombopenic purpura is reported by Gorham, Propp, Schwind and Climenko.⁴² These authors stress the close chemical relations between benzol, aniline, sulfanilamide and the other sulfonamide drugs and their often similar effects on the bone marrow. Of 8 patients developing thrombopenic purpura, 4 died. It is recommended that blood smears be routinely examined for a possible decrease in platelets during sulfonamide administration. Kracke and Townsend,⁴³ reporting 2 cases of thrombopenic purpura developing during sulfathiazole administration, further studied 23 patients under treatment with the drug. There was a possible slight reduction in platelet count on the third day of treatment, followed by a rather marked rise when the drug was discontinued. This may indicate a more frequent effect on the platelet precursors in the marrow than is customarily believed. The most likely mechanism however, is a hypersensitivity on the part of the bone marrow to the sulfonamides. This was demonstrated by Hurd and Jacox⁴⁴ in a patient who was found to be sensitive to both sulfathiazole and sulfadiazine following recovery from a severe thrombopenia that developed with sulfathiazole administration.

The occurrence of mild thrombopenic purpura during infectious states is not at all uncommon, particularly when there is splenomegaly — as in typhoid fever and malaria. In infectious mononucleosis, the platelets are characteristically normal in number to find a low platelet count in conjunction with abnormal lymphocytosis is ordinarily tantamount to making a diagnosis of acute leukemia. Rarely, however, thrombopenic purpura and infectious mononucleosis coexist. Tager and Klinghoffer⁴⁵ report

*Professor of clinical medicine, Tufts College Medical School; visiting physician and consulting hematologist, Joseph H. Pratt Diagnostic Hospital.

case of an infectious disease characterized by abnormal lymphocytosis and extreme thrombopenia, which suggested acute leukemia to most observers. Since, however, anemia was not present and the lymphocytes were extremely variable in size and shape, infectious mononucleosis was considered possible and this disease — or a similar one — proved to be present. Lymphocytosis and thrombopenic purpura not uncommonly go together, as noted some years ago by Minot.⁴⁶ I have found this abnormality in a number of cases of the idiopathic type of thrombopenic purpura, often in association with leukopenia, suggesting a possible splenic reaction on the bone marrow.

The spleen and the marrow are probably closely related, most likely by way of certain hormonal mechanisms. When the spleen becomes enlarged, as in cirrhosis of the liver, splenic vein thrombosis and Gaucher's disease, leukopenia and thrombopenia are frequently found. Although the blood in these cases shows diminished leukocytes and platelets, the marrow shows hyperplasia of both leukocytic and megakaryocytic elements. In idiopathic thrombopenic purpura, the marrow is crowded with megakaryocytes, although the blood may be completely devoid of their end products, the platelets. The striking effect of splenectomy may indicate that the fundamental abnormality of this disease is a disturbed function of the spleen, which can be cured only by removal of the offending organ. Occasionally, thrombopenic purpura complicates pregnancy; this may present a very difficult therapeutic problem. Palliation by transfusions may tide the patient over until platelets begin to be made spontaneously; some cases, however, fail to respond and splenectomy must be seriously considered, else the patient may die of hemorrhage. In a case reported by Urbanski and Hutner,⁴⁷ the patient was delivered despite the purpura, but nineteen days later there was severe bleeding from the uterus, controlled only when splenectomy was performed. At birth, the infant had a transient thrombopenic purpura, which lasted a few days. Subsequent to splenectomy, the mother had three normal full-term pregnancies in which the children were free of purpura. However, in a case reported by Whitney and Barritt⁴⁸ in which splenectomy for thrombopenic purpura was performed at the age of fourteen, two pregnancies terminated in the delivery of thrombopenic babies, both of whom died of hemorrhagic disease. It is to be noted that the mother in this case continued, despite her splenectomy, to have active thrombopenic purpura, as evidenced by a low platelet count, a prolonged bleeding time and a greatly diminished clot retraction; this is quite in contrast with the usually good results of splenectomy. It is evident that the same deleterious influence that results in thrombopenia of the mother may act on the bone marrow of the developing fetus, producing thrombopenic purpura.

Abnormalities of Capillary Walls

Abnormalities of the capillary wall may be caused by many diverse conditions, such as ascorbic acid deficiency, infections involving the capillaries directly, — subacute bacterial endocarditis, meningitis and so forth, — toxins — as in certain infectious states and in uremia — and more or less vague conditions of increased capillary permeability. The end result of the capillary abnormality is bleeding into the skin or mucous membranes (or internally in the various organs). Davis⁴⁹ classified 500 cases of purpura of the skin; 37 per cent — comprising so-called "purpura simplex," Schonlein-Henoch purpura, pseudohemophilia and so forth — were idiopathic. The remainder of the cases were symptomatic: that is, secondary to chemical, bacterial, infectious and other states. In any one patient, multiple factors may contribute to the purpura: arthritis, the menopause and other endocrine factors, infection, edema and orthostasis.

Davis⁴⁹ uses the term "purpura simplex" for those cases showing spontaneous ecchymoses of the skin in the absence of demonstrable hematologic abnormalities. These cases are usually present in women who complain of easy bruising and the appearance of ecchymoses without trauma. They have been called "devil's pinches," "dead man's nips" and "dead man's pinch." Davis has found in these cases not only a strong hereditary tendency but also a high incidence of rheumatic fever, rheumatoid arthritis or some other form of arthritis. The platelet count, coagulation time, bleeding time, prothrombin time and clot retraction are all normal, but the tourniquet and intradermal snake-venom tests are usually positive. Treatment with various endocrine products, vitamins C and P, snake venoms and so forth, has been used, but is of questionable value. Since the condition is ordinarily of little significance, reassurance is probably the best form of therapy.

A condition that has recently assumed increasing importance is that of pseudo-hemophilia (von Willebrand's disease, Glantzmann's disease, hereditary hemorrhagic thrombasthenia or athrombocytopenic purpura). In his book on the hemorrhagic disorders, Quick⁵¹ gives an excellent description of the condition, with tables differentiating it from other hemorrhagic conditions. This disorder, although by no means clear cut, is nevertheless of great importance to those who have it, since they bleed excessively from small operative wounds such as those caused by dental extractions and hemorrhoidectomy. Cronkite and Lozner⁵² make this point with reference to military medicine, and show how a great deal of bleeding from small trauma may occur without too much in the way of laboratory abnormalities, except a slight and variable increase in the bleeding time. In some cases, the hemorrhagic tendency is extremely severe and even hemarthroses, similar to

those seen in hemophilia, may occur. The history of a hereditary bleeding tendency, which is not sex linked, can be obtained in some cases. The chief recognizable abnormality is a definitely prolonged bleeding time in the presence of normal blood-platelet counts, normal clot retraction, normal coagulation time, normal prothrombin time and a normal tourniquet test. The bleeding time in the same patient at different times, by different technics and in different parts of the body is highly variable. Thus, one of my patients had a bleeding time of two and a half hours in one ear, twenty minutes in the other and a few minutes in a finger. In the ear that had bled for two and a half hours, the bleeding time some weeks later was only three minutes. An abnormality in capillaries and in capillary retractility has been postulated, principally by Macfarlane,⁵³ chiefly on the basis of studies of the capillaries at the nail bed and their response to trauma. Macfarlane found that the capillaries in this condition were of distorted and often bizarre forms and showed no tendency to contract after injury. In my own cases, however, no such capillary abnormality was demonstrable; furthermore, distorted and bizarre capillary loops without demonstrable hemorrhagic tendency are frequent in vasomotor conditions and certain psychoses. In a recently described case of idiopathic hypoprothrombinemia,⁵⁴ a bleeding abnormality similar to that of pseudohemophilia was found, and the author makes the point that the abnormal coagulation mechanisms in the latter disease are by no means worked out. With this I heartily agree.

Abnormalities in Circulating Coagulation Factors

Abnormalities in the circulating coagulation factors comprise hemophilia, hypoprothrombinemia, such rare conditions as fibrinopenia and those associated with the presence in the blood of a circulating antithrombic constituent.

Hemophilia. The etiology of the sex-linked hereditary hemorrhagic disorder known as hemophilia remains as obscure as ever. Is it a defect in thromboplastin, in a portion of the globulin fraction of the serum or, as Tocantins⁵⁵ has recently observed, an excess in circulating antithromboplastin? Howell,⁵⁶ Quick,⁵⁷ Ferguson^{57, 58} and many others believe that there is a defect in the liberation of thromboplastin from peculiarly resistant platelets. On the other hand, the group at the Thorndike Memorial Laboratory in Boston has presented apparently convincing evidence that platelet-free plasma and a euglobulin fraction of the plasma are effective in reducing the coagulation time in hemophilia.⁵⁹ It is possible that these seemingly divergent views are fundamentally related. Thus, in a more recent report from the Thorndike Memorial Laboratory by Tagnon, Davidson and Taylor,⁶⁰ there is described a proteolytic enzyme resembling trypsin in the plasma that is found to be reduced in preparations of hemophilic

plasma. In this paper, "globulin substance" is criticized as being far from a pure material. It should be noted that this concept is closely similar to that of Ferguson, who for several years has maintained that hemophilia is due to a deficiency in serum tryptase. A wholly new concept is that of Tocantins,⁵⁵ who claims that hemophilic plasma has an activity against certain thromboplastin solutions five to eight times as great as that of normal plasma. He concludes that an excess of antithromboplastin is probably the primary cause of the delay in the inception of clotting of hemophilic blood. Tocantins's conclusions are based on the collection of plasma under special precautions and its effect on the clot-accelerating action of certain aqueous extracts of brain tissue. His experiments must await confirmation before their relation to hemophilia can be completely ascertained. Another new concept regarding the etiology of hemophilia is supplied by Pennell,⁶¹ who claims that the coagulation of blood is dependent on a sudden and massive disintegration of platelets, that this occurs only when the platelets and red-cell surfaces are in contact (conjugation), that in hemophilia the phenomenon of red-cell-platelet conjugation is reduced, and finally that "the hemophilic's red cells may be responsible for the diminished red-cell-platelet conjugation in this disease." It cannot be denied that this is an ingenious theory, but it too requires a good deal of confirmatory evidence before it can be accepted.

The treatment of hemophilia also remains as difficult as ever, although the control of external local bleeding by means of thrombin preparations has proved successful in many cases, particularly in dental extractions. The original thrombin product, prepared as a pseudoglobulin fraction from rabbit plasma, has been found moderately effective, particularly when applied fresh from powdered material.⁶² Other perhaps more potent preparations are now in process of manufacture from both human and bovine sources. For internal bleeding in hemophilia, for bleeding in joints and for severe local and external bleeding, *fresh* whole blood, citrated or unmodified, is quickly effective. Bank blood must not be used. Dry plasma prepared from fresh liquid plasma is apparently just as effective as fresh blood⁶³; however, this type of dried plasma is not commercially available.

The value of oxalic acid and of injections of shepherd's purse is still highly questionable. Shepherd's purse is a common weed that according to Copley and Lalich⁶⁴ was used centuries ago as a hemostatic agent locally and internally. They state that this plant or its extracts when taken orally may exert a hemostatic effect.

Emergency and even elective surgery may be done in hemophilia if the patient is properly prepared by transfusions given prior to, during and after operation. In a recent case at the Boston Floating Hospital, a hemophilic child aged three required a mid-

thigh amputation because of gangrene of the foot resulting originally from a fall, with bleeding into the leg. The amputation was successfully carried out by dint of numerous transfusions, given both before and after operation. Baird and Fox⁶⁵ report a case of severe paratracheal hemorrhage in a hemophilic child, with recovery following tracheotomy, in which the bleeding was controlled by the use of large quantities of blood. Although the patient was only four and a half years old, the initial quantity of blood given was 950 cc., and this was followed by the daily administration of 500 cc. of blood for three days.

Hypoprothrombinemia. Two types of hypoprothrombinemia must now be discriminated: a clinical type that is the result of various etiologic factors and an artificial type that can be conveniently produced by the administration of dicoumarin. The development of knowledge regarding prothrombin deficiency and its relation to vitamin K represents a fascinating chapter in modern medicine. Hypoprothrombinemia is now known to occur as the result of severe dietary deficiency, in conditions of intestinal disease and malabsorption, in the newborn infant because of the lack of a beneficial intestinal bacterial flora, in severe hepatic disease and in obstructive jaundice.⁶¹ There has furthermore been described a condition of idiopathic hypoprothrombinemia in which the presence of a hemorrhagic disorder is associated with a greatly increased prothrombin time, although none of the above etiologic factors are present.⁶⁶ The treatment of hypoprothrombinemia has been fairly well standardized. Except in severe hepatic disease and perhaps in the idiopathic type, vitamin K is equally effective whether given orally, intramuscularly or intravenously. The routine use of the vitamin just before delivery has been widely recommended as of value in reducing the prothrombin time of the fetus. This method has much to recommend it because even though the mother is normal, the newborn infant may show a delayed prothrombin time. The presence of even incipient hemorrhagic disease may well contribute to cerebral hemorrhage, particularly if the delivery is a difficult one. On the other hand, Parks and Sweet⁶⁷ found no greater incidence of hemorrhagic disease in infants born of mothers who received no vitamin K antenatally than in those born of mothers who had received 5 mg. of the vitamin orally on admission to the hospital. Despite this report, it is probably best to give the mother 5 to 10 mg. of vitamin K intramuscularly just prior to delivery, thus ensuring an adequate prothrombin concentration in the fetus during its more or less arduous journey through the birth canal.

The prothrombin time is usually performed by the method of Quick, using rabbit brain as a source of thromboplastin. Fullerton,⁶⁸ and later Page and his collaborators,^{69, 70} have introduced the use of solutions of Russell viper venom (Stypven — Burroughs

Wellcome and Company) as a substitute for rabbit-brain thromboplastin. Page and de Beer⁷⁰ state, "The commercially available venom is convenient, quite uniform within and between batches, and, as originally packaged, stable for at least five years." The solutions retained their thromboplastin-like activity unimpaired for months at icebox temperature but suffered decomposition after about two months' exposure to the air at room temperature. Lyophilized rabbit brain as a source of thromboplastin is extremely potent and is now commercially available. Fractions sealed in vacuo and kept in the dark at 3°C. have, according to Hoffman and Custer,⁷¹ kept their potency for at least seventeen months. The latter authors describe a micromethod for the estimation of prothrombin in fresh capillary blood; although the test appears to be very accurate, it requires much special apparatus including a special pipette, a specially constructed heating unit and slide holder and a platinum rake.

The use of dicumarol to prolong the prothrombin time and total coagulation time was introduced by Bingham, Meyer and Pohle⁷² in the prevention of thromboses and as a substitute for heparin in other conditions. Bingham, Meyer and Howard⁷³ report that the drug should be used with caution and is contraindicated in patients with hemorrhagic tendencies or gross hepatic disease. The usual dosage was an initial administration of 5 mg. per kilogram of body weight, followed by a daily dose of 1.5 mg. per kilogram. On certain days no dose was given if the prothrombin time or coagulation time was too prolonged. Since there is a latent period in the development of delayed prothrombin and total coagulation times, heparin has been advantageously used for its immediate effect. To employ these measures with safety to the patient, the daily determination of prothrombin and coagulation times is imperative; the prothrombin concentration should be no lower than 25 per cent of normal, and the coagulation time should be no greater than fifteen to twenty minutes. Davidson and MacDonald⁷⁴ caution against the indiscriminate use of dicumarol. They found vitamin K of no effect as an antidote, and whole-blood transfusions had either no or only a transitory effect on the abnormal clotting mechanism in patients receiving the drug. Large-scale clinical studies have been made by Allen, Barker and Waugh⁷⁵ at the Mayo Clinic. Of 374 patients who were given the drug postoperatively to prevent thrombosis, only 3 developed thrombophlebitic lesions. The dicoumarin was administered orally, single doses of 200 to 300 mg. being given on the first day and 200 mg. on the second day. Subsequent daily dosage is based on the prothrombin time of the blood drawn that day, keeping the latter between thirty-five and sixty seconds. Wright and Prandoni⁷⁶ conclude that the therapeutic value of dicoumarin has as yet not been clearly established.⁷⁷

HEMOLYTIC SYNDROMES

As noted in the 1942 review, the hemolytic syndromes may be classified as acquired and hereditary, with a special grouping for hemoglobinurias. Familial spherocytosis (congenital or familial hemolytic anemia) is by no means the only type of hereditary hemolytic disease, since two other well-defined syndromes are present: a Mediterranean target-oval cell condition and sickle-cell anemia. The hemoglobinurias have been well described, and are of the following varieties: paroxysmal cold, paroxysmal nocturnal and march; in addition, hemoglobinuria regularly occurs in the presence of sudden intravascular hemolysis when the threshold value for hemoglobin in the plasma is exceeded.

Mechanisms

The mechanisms that initiate and carry through normal red-cell destruction are quite obscure, although one may speak of possible swelling and fragmentation of the red cell and of its total destruction in the reticuloendothelial system, more particularly in the spleen. In the acquired hemolytic types, it becomes more and more apparent that attempts to implicate some one mechanism such as agglutination, erythrosthesis or the activity of hemolysins stretch the point, since diverse mechanisms can all bring about the dissolution of the red cell.

Dameshek and Miller⁷⁸ studied the effects on red cells of simple lysins, complex hemolysins and agglutinins. Simple lysins act directly on the red cells, producing either complete hemolysis or spherocytosis. Complex hemolysins, such as immune hemolysins, first produce sensitization — that is, agglutination — by means of amboceptor and then hemolysis by means of complement. Agglutinins produce agglutination that results in hemolysis, probably because of several factors, important among which is that of mechanical trauma within the circulation. Both hemolysins and agglutinins act by injuring the red cells actively — the final stage of hemolysis taking place by different mechanisms. Other factors that are undoubtedly of importance are such physical ones as temperature and hydrogen-ion concentration.

In this paper, Dameshek and Miller contrast their "active" concept of hemolysis with the more "passive" one of erythrosthesis of Ham and Castle.⁷⁹ The latter investigators have stated that the hemolytic anemias are due to agglutination of red cells with subsequent stasis, to increased viscosity with stasis or to increased rouleaux formation with stasis. In other words, the feature most stressed is that of stasis. Yet in multiple myeloma, in which rouleaux formation is often extreme, and in polycythemia, in which stasis and viscosity are both very marked, hemolytic anemia rarely if ever occurs. Furthermore, such explanations are of no value in cases with a circulating autohemolysin, in paroxysmal cold hemoglobinuria, in paroxysmal nocturnal hemo-

globinuria and so forth. What is more, Shen, Han and Fleming⁸⁰ have recently demonstrated that the heating (and possibly searing) of red cells under conditions of severe burns is followed by spherocytosis and hemolysis. This is in line with Dameshek and Miller's previous investigations, which demonstrated that spherocytosis — the forerunner of hemolysis — can be experimentally produced by a variety of chemical, immune-body and physical agents. Napier and Sen Gupta,⁸¹ working in India have recently confirmed in monkeys this experimental work on hemolysins and hemolytic anemia in guinea pigs. The development of spherocytosis and of double-peaked Price-Jones curves is also described, together with careful statistical analysis of the data. Napier and Sen Gupta make the observation that although the life of the spherocyte may possibly be shorter than that of a normal cell, it cannot be considered as an immediate precursor of hemolysis. For this, other mechanisms (possibly the spleen) may be necessary. Spherocytosis is by no means pathognomonic of familial hemolytic anemia but occurs in many conditions, familial and acquired, in which active hemolysis is present. Thus, it is characteristically seen in the acute hemolytic anemia of sulfonamide administration.

The occurrence of hemolytic anemia in association with a circulating cold hemagglutinin has occasioned much recent interest. In 3 cases that I¹⁶ reported, sulfonamides had been given and it was difficult to state whether the sulfonamide had directly produced the hemolytic anemia, whether it had not been concerned at all or whether the combination of sulfonamide and agglutinin was responsible for the anemia. Some cases of acute hemolytic anemia have apparently arisen in primary atypical pneumonia simply in association with a high titer of cold hemagglutinin.¹³ We have recently been studying a patient who has a chronic hemolytic process in association with a very high concentration of cold hemagglutinin. Stats and Wasserman¹² in their recent exhaustive review of cold hemagglutination discuss the possibility that hemolysis occurs in such cases through the medium of mechanical trauma of agglutinated red cells.

Tompkins⁸² discusses the effects of repeated intravenous injection of lecithin in rabbits and their relations to lipoid-storage diseases and to hemolytic anemias. The lecithin not only accumulates in the reticuloendothelial system, more particularly in the spleen, but results in a slowly progressive hemolytic anemia associated with a slight increase in hypotonic fragility and an increased malleability of the cells, with a tendency to the formation of oval and even sicklelike forms. This effect may have some relation to normal hemolytic mechanisms because of the possibility that phospholipids in the circulation are adsorbed on erythrocytes and because lecithin is a well-known hemolysin. It is also in line with the

work of Freeman and Johnson,⁸³ who believe that lipid materials by entering the thoracic duct go indirectly into the circulation and affect the red cells by gradual swelling and finally hemolysis.

Also related to this general concept is the work of Collier, Allen and Swales.^{84, 85} In studying phenothiazine, which is used as an anthelmintic in horses, these investigators found that although it produced hemolytic anemia *in vivo*, it failed to do so *in vitro*. This chemical, however, had a strikingly accelerating effect on the lysis of red cells by saponin or lysolecithin, and the authors state that this property may be responsible for its *in vivo* effect in cases in which some lysolecithin is presumably present. Lee and Tsai⁸⁶ point out, however, that lecithin may be antihemolytic as well as hemolytic, this being dependent on such factors as concentration of cholesterol and temperature. Finally, Ponder⁸⁷ discusses the disk-sphere transformation produced by lecithin. It can easily be seen that much clarification is required for the mechanisms underlying hemolysis, even under normal conditions.

Clinical Syndromes

Hereditary types. Of the three hereditary forms of hemolytic anemia, *familial spherocytosis* is by far the best known; in fact, the term "congenital hemolytic anemia" is often applied to this well-defined condition, in which spherocytosis, increased hypotonic fragility and prompt cure by splenectomy are important features. The cause of the spherocytosis has not been established, although, since this abnormal red-cell feature can be so readily produced by the action of hemolysins, it seems logical to conclude that an abnormal hemolytic mechanism of some sort is present. Dacie and Mollison⁸⁸ showed that when normal red cells are introduced into the circulation of these patients, they have a normal survival time; conversely, spherocytes introduced into a normal person's circulation quickly disappear. Although these authors concluded that the basic abnormality is abnormal erythrocyte formation, the role of possible hemolytic mechanisms cannot be excluded, since it would naturally be expected that spherocytes, already being, so to speak, on the road to hemolysis, are more quickly destroyed in the intact spleen. In a further paper, in which curves of hypotonic fragility, the histology and physiology of the spleen and so forth are carefully analyzed, Dacie⁸⁹ showed that the spleen is unusually congested. Perfusion experiments with excised spleens did not demonstrate the cause of the congestion. Dacie concluded that the available evidence points to the presence of a hemolytic disorder based on abnormally hemolyzable red cells, and that the possibility of the presence of an abnormal hemolytic agent or metabolite cannot be ignored. This leaves the problem about where it was originally.

The presence in people of Mediterranean origin of anemia of varying degrees of severity, often slow-

ing apparently different clinical syndromes — from the severe and fatal Cooley's anemia to a mild hypochromic anemia or hypochromic erythrocytosis — has been discussed in previous reviews, and is described under the designation, "familial Mediterranean target-oval-cell syndromes," in a recent article.⁹⁰ These conditions appear to have as one of their fundamental characteristics an inherited abnormality of hemoglobin formation, with the result that the red cells are unusually thin and have the appearance of targets or bull's eyes in the stained blood films. Oval and elliptical cells are also frequent. Because the red cells are unusually thin, they are, in contradistinction to the spherocytes, abnormally resistant to solutions of hypotonic sodium chloride. Despite the hypochromic character of the anemia in most cases, there is no response to iron — apparently because the nucleated red cell cannot make or deposit sufficient quantities of hemoglobin within its cytoplasm. More severe cases have a hemolytic component, with icterus, splenomegaly and increased urobilinogen output present. Bone changes are found only in the most severe forms. In this paper, and in an exhibit at the 1942 meeting of the American Medical Association,⁹¹ the numerous resemblances between the essentially Mediterranean target-oval-cell syndromes and the essentially African (Negro) target-sickle-cell syndromes were pointed out. In both these conditions, unusual thinness of the red cells (leptocytosis) is prominent, with complete refractoriness to iron therapy. In both, it appears that the mating of two persons each of whom has a mild condition or trait may result in the presence of a severe condition in one or more of the offspring.

Smith⁹² confirms most of these findings in a study of sixteen families, and points out that recognition of the mild type depends solely on a careful study of the blood. This author objects to the designation of "target-cell anemia" for these cases, since target cells are by no means constantly present and are non-specific. Since, however, increased hypotonic resistance was always present, it is certain that the red cells were unusually thin, which amounts to the same thing. Leptocytosis, which indicates the presence of thin as opposed to thick red cells (spherocytes), may be a better designation. Familial leptocytosis is by no means nonspecific, although it must be conceded that target cells *per se* may occur in a number of diverse conditions.

That target-cell anemia may not be completely limited to people of Italian, Greek, Syrian or Portuguese origin is brought out by Schieber,⁹³ who reports 2 cases in a family of Buchara Jews. The author states that the ancestors of these people have been known to live on the shores of the Caspian Sea for many centuries, although in the dim past they must have originally wandered up from the Levant.

More and more cases of *sickle-cell anemia* are being reported in the white race, more particularly

in those of Italian origin. Morrison, Samwick and Landsberg⁹⁴ point out the common difficulties encountered in making the diagnosis of sickle-cell anemia in white people. Search for the sickling phenomenon, they say, should be undertaken in all cases of obscure hemolytic disorders, even in white patients. They state that in the presence of splenomegaly, a splenic puncture may demonstrate a far more marked sickling phenomenon than does the peripheral blood. Greenwald, Spielholz and Litwins⁹⁵ make similar observations and point out the relatively frequent occurrence of sickle-cell anemia among people of southern Italian and Mediterranean descent. Ogden⁹⁶ reports 9 cases of the sickling trait — 2 of them active sickle-cell anemia — in two white families. On the assumption that sickle-cell anemia is a national public-health problem, the author comes to the radical, possibly biased, conclusion that "intermarriages between Negroes and Whites directly endanger the white race by transmission of the sickling trait. . . . Such intermarriages . . . should be prohibited by federal law."

Acquired hemolytic disease. It becomes increasingly clear that most of the cases of hemolytic disease are not hereditary, but are due to a variety of etiologic factors, including hemolysins of immune body type, agglutinins, chemicals, bacteria and other organisms such as the malarial parasite. Some of the cases occur in association with a more fundamental disease (Hodgkin's disease, lymphoma and so forth). Singer and Dameshek⁹⁷ have termed these "symptomatic." Hemolytic disease of whatever cause is due to the breakdown of red cells, with the rapid liberation of hemoglobin (hemoglobinemia and hemoglobinuria) or its slow conversion into bilirubin. As direct evidences of increased hemolysis, Dameshek and his co-workers⁹¹ list the following: anemia, indirect bilirubinemia, hemoglobinuria, increased red-cell thickness, — that is, spherocytosis, — increased hypotonic fragility of the red cells and increased output of urinary and fecal urobilinogen. Of these features, the fecal urobilinogen output is by far the most important and most direct evidence of increased hemolysis; all the other features may be present in the absence of increased blood breakdown.⁹⁸ Indirect evidences of increased hemolysis are shown by increased bone-marrow activity, particularly by reticulocytosis and polychromatophilia, leukocytosis, polymorphonuclear and platelet increase and splenomegaly. Clinically, the combination of pallor and icterus should always make one suspect a hemolytic process, particularly if splenomegaly is present. Careful examination of the stained blood smear often shows the combination of small, thick, dense-appearing red cells and of large red cells that are bluish gray (polychromatophilic). The spherocytes indicate hemolysis; the large polychromatophilic cells (reticulocytes) indicate active regeneration on the part of the marrow.

Wilson and Mangun⁹⁹ report 3 interesting cases of acute hemolytic anemia with hemoglobinuria in fertilizer workers who were exposed to fumes decaying fish and impure sulfuric acid. In the hold of the ill-ventilated boats into which these men were sent, it is probable that arsine gas was generated. Arsine has long been known as a strong hemolytic agent. Wilson and Mangun demonstrated an active hemolysin in the globulin fraction of the serum; since complement was not necessary, this was not of the immune-body type. They postulated that the arsine gas, entering the lungs, entered into a loose combination with blood protein, so altering it as to give it an active hemolytic property, independent of the presence of arsenic itself. An important clinical fact brought out in these cases is the necessity for maintaining an alkaline urine in cases with hemoglobinuria to minimize precipitation of hemoglobin products in the renal tubules.

Acute hemolytic anemia of the newborn — erythroblastosis fetalis — is apparently due to an agglutinative-hemolytic reaction between the anti-Rh agglutinin of the mother's serum and the newborn infant's Rh+ red cells. Dameshek, Greenwald and Tat¹⁰⁰ found that the output of fecal bilirubin and urobilinogen was distinctly increased in these cases; all the other indications of an acute hemolytic process were also present, including biphasic Price-Jones curve of red-cell diameters, marked regenerative activity on the part of the bone marrow and so forth. Reisner,¹⁰¹ who studied the red-cell diameters of 12 cases of fetal hydrops and of icterus gravis, found in all but 1 characteristic biphasic curves resembling those observed in experimental hemolytic anemias due to antigen-antibody reactions; it is probable, as stated above, that similar mechanisms are operative in the human cases. Transfusions with Rh- blood are often quickly effective in controlling the anemia and resulting in a favorable therapeutic result. If the mother is known to be Rh-, it is certainly wise to have Rh- donors on hand for possible immediate use in the newborn infant.

I¹⁰² have recently stated my views on the management of acute hemolytic anemia and the hemolytic crisis as based on the study of 25 cases. Such cases are serious therapeutic problems demanding careful and sustained attention. Unusual heed must be paid to blood-grouping technics, and search must be made for atypical hemolysins and agglutinins. Because of the possibility of reactions to as few transfusions as possible should be given. Immediate consideration of splenectomy should be taken up, since continued procrastination in the hope that something will turn up may result in a blind alley from which there may be no escape but splenectomy done as a desperate measure of last resort. The familial cases in crisis uniformly do well with splenectomy, but in the acquired cases prediction as to ultimate recovery is difficult. In 1

CASE 30181

PRESENTATION OF CASE

First admission. A twenty-six-year-old housewife was admitted to the hospital because of abdominal pain.

The patient had been in good health until about twenty-one months before entry, when, following a two-day history of epigastric pain gradually localizing in both lower quadrants and associated with severe cramps on urination and one episode of vomiting, she was admitted to a community hospital. A pelvic abscess was drained through the vagina, and vaginal smears were said to have shown many gram-negative diplococci. About a month later a right subphrenic abscess was incised in the same hospital, and she was finally discharged after two months. She was then fairly well until seven months before admission, when she underwent an appendectomy in the same hospital. She remained in moderately good health until two months prior to entry, when she developed a dull grinding ache in the lower abdomen. Abdominal exploration at that time showed an absolutely "frozen" pelvis and many adhesions between the intestines. While the adhesions were being separated a small opening was made in a loop of small intestine. This was closed. She recovered from the operation and was discharged home. Two weeks before admission to this hospital she developed severe, crampy, low abdominal pain, which was associated with nausea but no vomiting or changes in the bowel habits. There was considerable pain in the back, urinary frequency and leukorrhea.

Physical examination showed a well-developed, fairly well-nourished woman. The heart and lungs were normal. There was a firm, tender, suprapubic mass, which extended higher on the left than on the

right. Pelvic examination showed a small cervix. The uterus was forward, freely movable and not attached to the mass. The mass was tender, "in and out of the pelvis" and probably cystic.

The blood pressure was 112 systolic, 75 diastolic. The temperature was 99.6°F., the pulse 70, and the respirations 20.

Examination of the blood showed a red-cell count of 3,600,000, with 10 gm. of hemoglobin. The white-cell count was 21,400, with 70 per cent neutrophils. An intravenous pyelogram was negative. Above the bladder there was an enlarged shadow having the appearance of an enlarged uterus. In connection with this there was an ill-defined, soft-tissue shadow extending out of the pelvis, especially to the left. A barium enema showed the same mass displacing the sigmoid to the left. A tuberculin test in dilution of 1:100,000 was negative.

The patient continued to have abdominal pain. A Miller-Abbott tube was passed, with considerable relief. She was given several transfusions and 12.5 gm. of sulfasuccidine daily, and on the eighth hospital day a laparotomy was performed. The small intestine was matted down in the midabdomen by many adhesions. The uterus, both tubes and ovaries appeared normal. The left ovary was slightly enlarged. It was impossible to mobilize the sigmoid. Both the sigmoid and bladder were accidentally opened and sutured, and the abdomen was closed. Peritoneal culture was negative. She had a slightly stormy postoperative course and was given several transfusions and 4 gm. of sulfadiazine daily. She was discharged on the fifteenth postoperative day.

Second admission (three months later). Following discharge the patient continued to have bouts of sharp, steady, low abdominal pain, pain in the bladder on urination and occasional bouts of fever (102°F.) with chills. The vaginal discharge continued.

Physical examination showed marked tenderness in both lower quadrants, more on the right than on the left, without much spasm. A poorly defined moderately tender mass was present in the left lower quadrant. Pelvic examination revealed pain and tenderness on motion of the cervix. In the left vault was a tender soft mass that seemed to rise out of the pelvis to the umbilicus. The right vault was clear but tender.

The blood pressure was 116 systolic, 72 diastolic. The temperature was 100°F., the pulse 70, and the respirations 20.

*On leave of absence.

Examination of the blood showed a red-cell count 3,720,000, with 65 per cent hemoglobin. The white-cell count was 14,150. The urine was normal, was a roentgenogram of the chest. A tuberculin test in dilution of 1:1000 was negative.

The patient was given several transfusions, placed on a high-calorie, high-vitamin diet and discharged to a nursing home.

Final admission (five months later). Following discharge she continued to have episodes of low abdominal pain. She lost about 15 pounds of weight and was bedridden most of the time. She drained considerable purulent material from the vagina, requiring five pads daily. Two or three days before surgery she began to have increasingly severe, constant, right lower abdominal pain. There were anorexia and some nausea, but no vomiting.

Physical examination showed a pale, thin woman who looked chronically ill. Exquisite tenderness and spasm were present over the right lower quadrant, where a round mass about the size of a grapefruit was palpable. Pelvic examination showed a profuse purulent discharge, a large tender fluctuant mass on the right and a firm, apple-sized, tender mass on the left.

The blood pressure was 94 systolic, 54 diastolic. The temperature was 102°F., the pulse 110, and the respirations 24.

Examination of the blood showed a red-cell count of 3,250,000. The white-cell count was 23,800. The urine gave a + test for albumin, and the sediment contained 30 to 40 white cells per high-power field.

The patient was given a transfusion of 500 cc. of whole blood. Incision and drainage of a pelvic abscess was done vaginally, yielding 200 cc. of foul thick pus on the left and a small amount of clear brown fluid on the right. On the fourth hospital day incision and drainage of the abscess in the right lower quadrant was done, yielding a moderate amount of thin, clear, yellow-red fluid. Both cultures showed a few colonies of *Staphylococcus albus* and of nonhemolytic streptococci. Drainage through the vagina was profuse. The patient continued to have a fever of 101 to 102°F. She was treated with an abdominal heat cradle, repeated transfusions and sulfadiazine.

On the thirty-first hospital day an exploratory laparotomy was performed.

DIFFERENTIAL DIAGNOSIS

DR. WALTER E. GARREY: The first laparotomy here is helpful, because they apparently did get through the dense adhesions that had been found previously in the community hospital only to find that the uterus, tubes and ovaries were normal.

May we see the x-ray films?

DR. MILFORD SCHULZ: This is one of the films of a roentgenogram and shows an essentially normal upper urinary tract; there does seem to be a soft-tissue

mass arising in the left side of the pelvis. Here is another film with a curious metallic foreign body with an accretion about it lying in the pelvis, not in the bladder or in the uterus. It is present in all the films.

The film of the chest is merely confirmatory of negative findings.

DR. GARREY: I believe the best way to handle this case is to jump in feet first and try to account for the disease of the peritoneum that caused dense adhesions, a friable bowel, because of which several operators entered the small bowel, large bowel and bladder in their efforts to separate the adhesions, and loculated collections of fluid, which seem to have varied in their character and in their location from time to time.

Before I saw the x-ray films I thought this woman had tuberculosis of the peritoneum, although I should have to account for the negative tuberculin test. I still think so, but I had not heard about this metallic foreign body. In seeking for the cause of a foul purulent discharge and recurring foul abscesses low in the pelvis, foreign body is one of the first things that come to mind. It is possible that some part of a drain or other material had been introduced during one of the earlier operations and had persisted in the cul-de-sac as a foreign body. If that were the case, I believe we should have to make a double diagnosis, tuberculosis and foreign body. So much for what seems the most likely possibility.

The pelvic causes are reasonably well ruled out by the operator who saw the pelvis when the patient was operated on in this hospital. It is inconceivable that she had a gonococcal pelvic peritonitis and salpingitis at the time of the first operation, a little over a year and a half before she came in. Could she have had such an infection and not have had visible damage in the tubes and perioophoritis? I doubt it. I also think it unlikely that the gonococcus could have caused subphrenic abscess, although it may even cause perihepatitis. Perhaps the gram-negative organisms that were allegedly found at the other hospital were due to gonococcal infection of the lower genital tract. Perhaps they were not truly gram-negative diplococci of the gonococcal variety. I think, but this is only a guess, that the appendix was probably the cause of all this trouble and that they later took it out, as one does for a perforated appendix in which the abscesses have been previously drained.

Of course endometriosis is a cause for dense adhesions and persistent trouble in the lower abdomen, but such a diagnosis is ruled out by the examiner who found normal adnexa at operation.

An infected dermoid cyst came to my mind as a cause for persistent pus. Perhaps such a cyst ruptured and spilled out its contents; but that is most unlikely. If she had had hydatid disease scattered through the abdomen, we should have heard some

mention of a well-encapsulated cyst rather than the story of dense and matted adhesions. I do not believe that the persistent fluid collections in the lower abdomen were caused by an intrinsic lesion of the gastrointestinal tract. The patient was not of the age group in which diverticulitis is commonly found, and nothing of this nature was noted on barium enema at the first entry.

Regarding neoplasm, one can remotely conceive that she had a mucous cyst of the appendix that had ruptured at the early operation and that pseudomyxoma spread through the abdomen, but I believe that they would have found some of the myxomatous material at operation here and that we should have heard of it in the findings that are given us.

If she had a tuberculous peritonitis, would it be possible for her to have had a negative tuberculin test, once in a high dilution and once in a fairly concentrated dilution? I think that it would be if she had a persistent focus of infection and had thus been able to desensitize herself. I have been told that terminal and fairly massive cases of tuberculosis often give a negative tuberculin test. Is that correct, Dr. Means?

DR. J. H. MEANS: I think so.

DR. GARREY: So I think that the patient did have a tuberculous peritonitis to account for the abdominal masses, the clear, free fluid and, later, the draining free fluid, the dense adhesions and the friable bowel. Perhaps she had a fistula in the sigmoid that communicated with a caseous mass. It also looks as if there was a foreign body, which may have been at the bottom of the last episodes, particularly the pelvic abscesses.

My diagnosis is tuberculosis of the peritoneum and probably a foreign body in the lower abdomen.

DR. MEANS: Is there any possibility of actinomycosis rather than tuberculosis? There was a lot of pus.

DR. GARREY: I thought of that and should have mentioned it. If she had had actinomycosis of this long duration there should have been extensive tissue destruction, and an actual fistula to the outside should have developed as a result of the destructiveness of that process.

CLINICAL DIAGNOSIS

Chronic pelvic inflammatory disease.

DR. GARREY'S DIAGNOSES

Tuberculosis of peritoneum.

Foreign body in pelvis?

ANATOMICAL DIAGNOSIS

Actinomycosis of fallopian tubes and ovaries.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: At operation the uterus and both tubes and ovaries were removed.

The tubes were thick and dilated and covered by firm fibrous adhesions, the right one more so than the left. The right ovary was intimately adherent to the tube and was enlarged. When this was cut into a fair amount of dirty gray, somewhat purulent material exuded; similar material was also found on the tube. Microscopic examination showed the lumen of the tube to be full of pus and scattered colonies of actinomyces. The latter were also found in the ovary.

DR. LELAND S. MCKITTRICK: The medical department is doing well.

DR. CASTLEMAN: I believe that at the time of first admission here Dr. Arthur W. Allen suggested actinomycosis; the organisms were hunted for but not found.

DR. GARREY: How long do you think she had actinomycosis?

DR. CASTLEMAN: I do not know. It is a bit surprising that there were not more lesions in the pelvis at the time of the first operation here, but there were so many adhesions that apparently they were unable to explore the pelvis thoroughly.

What do you think about the origin, Dr. Leland S. McKittrick?

DR. MCKITTRICK: I was wondering where it came from. There is the first episode to explain. She might have had a perforated appendicitis at that time and that might have been the origin of actinomycosis. Is that possible?

DR. CASTLEMAN: That is my feeling.

DR. MCKITTRICK: The whole story is a more or less confusing affair, but that is a possible explanation. Actinomycosis certainly follows, at least infrequently, work on the bowel, particularly operation for perforation of the appendix.

DR. CASTLEMAN: It is interesting that during the last two months we have had three cases of actinomycosis.

CASE 30182

PRESENTATION OF CASE

A fifty-nine-year-old business executive was sent to the hospital by his physician because of acute difficulty in breathing.

The patient had been in excellent health and a very hard worker until six years before the present episode when he developed "leg ache," insomnia and tiredness. He was seen by his physician who found a slightly enlarged heart. There was bigeminy and a rough apical systolic murmur. The blood pressure was 150 systolic, 70 diastolic. The white cell count was 7900, with 64 per cent neutrophils. The red-cell count was 4,810,000, with 80 per cent hemoglobin. The nonprotein nitrogen was 33 mg. per 100 cc. The urine was normal. A blood Hinton test was negative. An electrocardiogram showed normal rhythm, with a rate of 68. The PR interval

as 0.16, and the QRS interval 0.07 second; T_1 and T_2 were upright, T_3 diphasic and T_4 inverted. There were slight left-axis deviation and ventricular extrasystoles. The T waves in Lead 2 were somewhat abnormal (there was a possibility that the lead wires in Lead 1 were crossed).

The pain in the legs continued; he was seen by various specialists during the following two years and obtained slight improvement by a leg bandage. Four years before the present episode he developed pain in the low back, and finally had an operation for a ruptured intervertebral disk, with apparent improvement in the back pain. The pain in the legs persisted, however, even with high-calcium therapy. An electrocardiogram one year before the present attack showed the same recording as before. There were frequent ventricular premature beats. The T waves were upright. Some slurring and prolongation of the QRS complex was seen. A chest roentgenogram six months before the present illness showed slight cardiac enlargement. The heart was a little wide across the auricles.

The patient remained in an essentially unchanged condition until five days before the present episode, when, after running for a train, he became breathless. In the next few days he had several attacks of mild dyspnea. One morning after severe dyspnea of four hours' duration, which had awakened him from sleep, he called his family physician.

Physical examination showed a well-developed, well-nourished, moderately dyspneic man. The cervical veins were slightly prominent. The left border of cardiac dullness was 9 cm. to the left of the midsternal line in the fifth space. The rate was irregular, with frequent extrasystoles. The pulmonary second sound was greater than the aortic. A loud (Grade IV) harsh, apical, systolic murmur was transmitted posteriorly. There was a slight thrill at the apex, but no gallop rhythm. The pulse was full. Examination was otherwise negative. The blood pressure was 130 to 160 systolic, 70 diastolic. The apical pulse was 84, the radial pulse 72. The temperature was normal.

Examination of the blood showed a hemoglobin of 90 per cent. The white-cell count was 7400, with 54 per cent neutrophils.

He was given 0.1 gm. of morphine hydrochloride, with instantaneous relief. He had a second, but much milder, attack of breathlessness at 5:00 o'clock the next morning, and three mild attacks the following day. He was then placed on $1\frac{1}{2}$ gr. of digitalis three times daily and on 3 gr. of quinidine three times a day for the irregularity. His condition improved definitely until the eighth day of his illness, when he had considerable air hunger associated with pounding and irregularity of the heart beat. Examination showed definite bigeminy, with the alternate beats not coming through. The rate at the wrist was 45. It was found that air hunger, irregularity of the rhythm and pounding appeared

when he lay down, but that these disappeared and bigeminy was resumed when he sat up. The digitalis was stopped because he had received a total of 18 gr. He developed pain in the legs, but no evidence of phlebitis could be found. In the next four days he had periods of quadrigeminal rhythm, — that is, three normal beats and then an extrasystole that did not get through to the wrist, — alternating with bigeminy and periods of air hunger and pounding when he slumped down. On the fourteenth day of his illness he was quite weak and complained of sleeplessness; he was given 50 mg. of Demerol. On the evening of the fifteenth day, while being read to by his wife, he complained of not being able to get his breath, took four or five gasps and died within a few seconds. When seen by his family physician a few minutes after that, no dilated neck veins were found.

DIFFERENTIAL DIAGNOSIS

DR. CONGER WILLIAMS: We are not told whether the leg ache resulted from exercise, when it occurred and so on. Such pain in the leg might mean the onset of intermittent claudication due to arteriosclerosis in the extremities, or it might mean thrombophlebitis. But I judge from the long duration and the absence of mention of swelling that the ache did not mean thrombophlebitis.

It is possible that the back pain was the result of a ruptured intervertebral disk, whereas the leg pain was due to peripheral arteriolar disease or thrombophlebitis.

Have we the x-ray films here?

DR. BENJAMIN CASTLEMAN: No; they were taken outside.

DR. WILLIAM B. BREED: Dr. Holmes interpreted the x-ray findings.

DR. WILLIAMS: "The patient remained in an essentially unchanged condition until five days before the present episode, when, after running for a train, he became breathless." This is the first sign of anything suggesting changes in the cardiac status. We have the statement that six years previously a loud, rough, apical systolic murmur was heard, which was still present at the time of this examination. The onset of dyspnea with exercise suggests cardiac failure. The subsequent attacks were not necessarily related to exercise.

We are told that the systolic murmur was transmitted posteriorly. I wondered about that statement. Does it mean transmission to the axilla or all the way around to the lung bases and back? That distinction is of some importance in making a differential diagnosis.

DR. PAUL D. WHITE: All the way around to the lung bases.

DR. WILLIAMS: The relation of bigeminal rhythm to posture is interesting. Change in position with assumption of the horizontal would make the more breathless, and might speed up the

pulse rate. With a faster pulse and shorter diastole, premature beats are less likely to occur. We know that he had previously had an irritable ventricle and was subject to attacks of ventricular premature beats. It might be that posture, either through its effect on congestive failure or possibly from reflex effect, modified in some way the formation of premature beats. It is well known that certain cases with tachycardia are affected by posture. I have seen the frequency of formation of ventricular premature beats altered by a change in position.

In considering the differential diagnosis I think that we have rather good evidence for the existence of heart disease. Can the whole picture be explained by assuming that he had heart disease alone, or must we assume that he had other complications in addition to heart disease? Certainly the presence of a loud apical systolic murmur over a period of six years is good evidence for heart disease, and in a man of this age the presence of such a murmur, even though it is not heard in the aortic area, always makes one suspicious of aortic stenosis. This is particularly true in the presence of emphysema, when the base of the heart may be some distance from the sternum, interfering with the transmission of the murmurs to the aortic area. It does not happen so often in thin patients. Another thing that inclines me to a diagnosis of aortic stenosis is the clinical course. In the first place he had only slight, apparent enlargement by x-ray examination six months before the final episode began. In aortic stenosis one may get considerable hypertrophy of the ventricular wall before any enlargement becomes evident by x-ray. The fact that he had few symptoms until the time of the final episode is consistent with aortic stenosis. The blood pressure in this case was not the typical blood pressure of advanced stenosis of the aortic valve, but that again does not rule out the diagnosis because it may occur in association with hypertension. Another thing in favor is the rather indefinite character of the electrocardiogram. It certainly did not give any specific diagnostic lead, most of the abnormality occurring in Lead 2 or 3. Aortic stenosis may give a variable electrocardiographic picture. It often is not of much help in making a diagnosis, and may not show evidence of left ventricular strain. Certainly this electrocardiogram did not show left-axis deviation, and did not have the characteristics of left ventricular strain. Another thing in keeping with the diagnosis is sudden death, patients with high-grade aortic stenosis often dying suddenly. Of course some are prone to fainting attacks, but it is not necessary in patients who die suddenly from this disease to have had previous fainting attacks.

The fact that the murmur was heard in the back is against the diagnosis of aortic stenosis. Well-transmitted aortic systolic murmurs are heard in the axilla but not in the back. Also against the

diagnosis is the fact that the aortic second sound was heard. That does not rule it out, however.

If the patient did not have aortic stenosis, what caused the apical systolic murmur? I am not able to say. I believe that he almost certainly did not have mitral regurgitation on the basis of old rheumatic infection. My main argument against that is the fact that at no time did he show evidence of marked left ventricular enlargement. Had such a lesion been present for several years, particularly a lesion of sufficient degree to produce a murmur this loud, one would expect to see considerable enlargement, both of the left auricle and ventricle. The x-ray report states, "The heart was a little wide across the auricles." I assume that this was in the posteroanterior view. The auricles are not mentioned specifically, which is not particularly helpful.

One must consider the possibility of cardiac dilatation to explain the murmur, but there are several things against that. One is the duration. We know that the murmur had been present for six years, and yet the degree of cardiac enlargement was never very great. So I think we must assume that in all probability he had a valve deformity to account for this murmur. I find it hard to account for the murmur on the basis of any disease in the mitral valve, and I certainly can think of no congenital lesion that would fit in with this murmur and also with the findings in the electrocardiogram. I did consider the possibility of coarctation of the aorta, but certainly there is nothing to support that diagnosis. I also considered the possibility of whether this man had, in addition to a valvular lesion, coronary heart disease. It is quite likely that he did, although we have no objective evidence for it. One cannot, however, explain the cardiac enlargement and subsequent events on the basis of coronary heart disease alone. Ordinarily when one sees a significant enlargement of the heart in the course of coronary heart disease, there has been at least one myocardial infarction at some time in the past. We have neither electrocardiographic nor clinical evidence to support that diagnosis.

Then of course there is one condition outside of the heart which we must consider in any acute cardiac diagnosis — namely, pulmonary embolism. There are a number of things in this man's story and findings that suggest pulmonary embolism. In the first place we have a rather vague story of pain in the leg, which might have meant thrombophlebitis, although at no time was there objective evidence of such. It is possible to have large pulmonary emboli without any sign of thrombophlebitis in the leg; in fact it is a fairly common occurrence. That might explain the findings of distended neck veins, the loud pulmonic second sound and finally the sudden death, assuming that he had one embolus or more at the beginning of the final episode and another at the end. But I was not so satisfied with that diag-

is as I was with the diagnosis of heart disease to explain the whole thing. I still cannot think of anything that fits the findings quite so well as aortic regurgitation, in spite of the fact that the murmur was heard in the aortic area.

DR. BREED: When I first saw this patient a number of years ago I considered the distinct possibility of some congenital lesion. He was not really a cardiac patient until a short time before his death. I considered thrombophlebitis seriously, and I might say that this question of the pain he had in his legs could be corrected. It was not pain. It was a feeling of discomfort and tension in his calves, which I thought of him from sleeping. It should not be dignified with the name of pain.

There is another point that I think is important to bring out: this murmur was sharply localized at the apex and was associated with a systolic thrill in the same area; the base of the heart was practically free from murmur and absolutely free from thrill. The murmur was transmitted directly up to the base of the left lung.

DR. WHITE: I wish Dr. Williams had been there with his stethoscope. It is sometimes impossible to describe murmurs adequately. You have to hear them. This murmur was practically entirely systolic, and it was loud. I felt a slight thrill at the apex. The murmur was not heard along the upper back over the spine, but was well heard at the bases. I thought that that distinction was important enough to allow us to decide that the valvular defect was mitral regurgitation rather than aortic stenosis. Had Dr. Williams been there he would, I think, have voted for mitral rather than aortic origin of the murmur. In middle-aged and older men, however, aortic stenosis, rather than mitral regurgitation, is usually responsible for loud murmurs that have been present for years.

This patient had had no rheumatic history. He had tonsils taken out as recently as 1937 and had had a life-insurance examination ten or fifteen years previously; but the murmur had been present for years before the final illness.

It was also important to consider the arrhythmia, and we thought that, in addition to the large doses of digitalis along with bed rest, that he was having for congestive failure, he should also receive quinidine, which ought to help to prevent a more serious disturbance of rhythm. Such a disorder of rhythm—namely, ventricular fibrillation—was one of the things that we thought of as a possible cause of his death. He was always afebrile. Nevertheless, if we were a rheumatic heart, whether aortic or mitral in type, there might have been a recurrent nodal myocardial involvement to explain the paroxysmal failure that came on. On the other hand, the acute physical strain when he ran for the train could have precipitated the illness—an unusual case, after which the present illness started.

DR. BREED: I was more impressed than Dr. White was with the association of the arrhythmia and what the patient called air hunger. I saw him more frequently and watched him with that in mind. The change in position with relief of the air hunger and return to bigeminy, as opposed to the grossly irregular rate when he was having the air hunger, was very impressive.

DR. WHITE: He was a nervous man and sensitive to the arrhythmia. That may have entered into the picture some.

DR. WILLIAMS: I should like to ask Dr. White a question. If you thought that this was mitral regurgitation, might the apparent failure have represented something else—such as pulmonary embolism?

DR. WHITE: We had seriously thought of it but did not enter it as a diagnosis. We also thought of coronary complications, but found no proof of them. The electrocardiogram was never that of coronary heart disease.

DR. WILLIAMS: Did you believe that the x-ray changes were enough to account for a diagnosis of cardiac failure on the basis of a lesion involving the mitral valve?

DR. WHITE: We did not have an x-ray examination after the heart began to fail.

DR. WILLIAMS: The note made on final physical examination states that the left border of dullness was 9 cm. to the left of the midsternal line, which does not suggest much enlargement.

DR. WHITE: The left border was difficult to find, but it seemed definitely beyond the normal position.

CLINICAL DIAGNOSES

Rheumatic heart disease, with mitral regurgitation.
Congestive heart failure.
Ventricular tachycardia or fibrillation, coronary occlusion or pulmonary embolus?

DR. WILLIAMS'S DIAGNOSES

Aortic stenosis (? rheumatic or calcareous).
Cardiac enlargement.
Congestive failure.
Pulmonary embolism?

ANATOMICAL DIAGNOSES

Rheumatic heart disease, with mitral regurgitation.
Cardiac hypertrophy.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: At autopsy, the heart of this man weighed 550 gm., a little under twice what it should weigh. The enlargement was uniform throughout all chambers. The right ventricular wall, however, was not hypertrophied, measuring only 3 to 4 mm. The left ventricular wall was definitely hypertrophied, measuring 17 to 18 mm. There was no

coronary disease. The pathology was limited to the mitral valve, which was definitely fibrous (Fig. 1). Some of the chordae tendineae were thick and slightly shortened, but the circumference of the

This is a much rarer type of congestive failure and death in middle-aged and older men than is the due to aortic stenosis, the chances ordinarily being 10 to 1 in favor of aortic stenosis; it seemed to

FIGURE 1. *Photograph of Mitral Valve.*

valve was markedly lengthened, measuring 15.2 cm. This was, then, a case of true mitral regurgitation — one of the few that we have had here as extensive as this. There was no disease of the aortic valve, and the myocardium showed no evident Aschoff nodules. The exact cause of death is still a mystery, but I suppose it was due to ventricular fibrillation or something of that nature.

DR. WHITE: That was our conclusion; he had probably not received enough quinidine to prevent fatal arrhythmia. He may have had ventricular tachycardia for a few seconds before the ventricles fibrillated.

at the time that the murmur and its transmission were significant.

DR. CASTLEMAN: At the time of autopsy there was little evidence of congestive failure. The liver showed only slight congestion.

DR. BREED: I was convinced before his death that the mild congestive failure from which he had suffered had been overcome and that, at the time of death, he was not suffering from congestive failure as such.

DR. WHITE: He was much better in that respect. He had improved quickly under treatment with digitalis and rest.

ANNUAL MEETING

THE one hundred and sixty-third anniversary
of the Massachusetts Medical Society will be held
at the Hotel Statler, Boston, on May 22, 23 and 24;
the program of the meeting appears elsewhere in
this issue of the *Journal*.According to the custom of the past two years,
the annual meetings of the supervising censors and
of the Council will be held in the late afternoon and
evening, respectively, of Monday, May 22, the day
before the opening of the regular sessions.The scientific program set up by the Committee
on Arrangements covers a wide variety of interest-
ing and timely subjects that will be discussed by
authoritative specialists.

The first morning will be devoted to a symposium
on war injuries, including venereal disease, wound
surgery, reconstructive surgery, the use of physical
therapy, and psychiatric casualties and their treat-
ment. Following the business portion of the annual
meeting of the Society, the annual oration will be
delivered by Dr. Joseph C. Aub. The afternoon
session begins with a group of papers on miscel-
laneous topics and ends with the Shattuck Lecture,
which will be given by Dr. Alfred Blalock, surgcon-
in-chief at Johns Hopkins Hospital and professor
of surgery, Johns Hopkins University School of
Medicine, the title being "A Consideration of Cer-
tain Recent Advances in Surgery." The annual
dinner of the Society will be held that evening; the
president, Dr. Roger I. Lee, will preside, and the
guest speakers will be the Honorable Leverett
Saltonstall, Governor of Massachusetts, and Bill
Cunningham, the well-known columnist of *The
Boston Herald*.

The morning program for the second day com-
prises five papers on subjects of general interest and
a symposium on gall-bladder disease, including the
medical, surgical and radiologic aspects followed by
a question-and-answer period. At noon, the sec-
tions will hold luncheon meetings, and at each a
short talk is scheduled. The afternoon session will
end with a panel discussion on the selection and use
of new chemotherapeutic agents, under the chair-
manship of Dr. Chester S. Keefer.

The scientific and technical exhibits, particularly
the latter, will be more extensive than ever before.
Pharmaceutical houses have made a tremendous
contribution to the war effort, — in fact, one whose
significance and value can never be appreciated
until the ban of censorship has been lifted, — and
what they have accomplished and are accomplishing
deserves proper recognition by the medical pro-
fession, which can best be shown by visits to the
booths of the commercial exhibitors.

Other attractions include the usual continuous
motion-picture program on both days.

It is obvious that the Committee on Arrangements,
composed of Dr. Gordon M. Morrison, chairman,
and Drs. Roy J. Heffernan, Sidney C. Wiggin,
Richard I. Smith and G. Guy Bailey, has put a large
amount of time and thought in making the plans

for this meeting. Owing to the shortage of physicians, there is an increasing demand for efficient medical practice, and all members of the Society should welcome the opportunity of learning the most up-to-date methods from those who are qualified to discuss them. A good attendance seems assured.

JOURNAL OF NEUROSURGERY

THE publishing of a new journal devoted to neurosurgery adds to the firm foundation of this branch of medicine.¹ Neurological surgery developed largely in this country as the result of the stimulus given to it by Harvey Cushing, who began publishing papers on the subject as early as 1900 and continued up to the time of his death in 1939.² A society of neurosurgeons named in his honor has now established a journal with an editorial and advisory board that reflects the widespread interest in this subject. The chairman of the board is Dr. Gilbert Horrax, of Boston, long associated with Dr. Cushing at the Peter Bent Brigham Hospital. Other members are from Chile, Canada, England and Sweden. It is presumed that after the war representation from other parts of the world in which neurosurgery flourishes will appear on the editorial committees. The managing editor, Dr. Louise Eisenhardt, of New Haven, Connecticut, was also closely associated with Dr. Cushing for many years, and she collaborated with him in his final great volume reporting his surgical experience with meningiomas. Dr. Eisenhardt is head of the Brain Tumor Registry at the New Haven Hospital, an undertaking begun by Dr. Cushing, where many specimens from other clinics are examined yearly and compared with those already on file.

In the first number of the *Journal of Neurosurgery*, Dr. Horrax describes some of Harvey Cushing's contributions to the subject, reviewing the development of the technic of surgical exploration of the cranial contents by this master. Another paper deals with fibrin foams as hemostatic agents and with fibrin films in the repair of dural defects and in the prevention of meningocerebral adhesions; the authors are Dr. Franc D. Ingraham and Dr. Orville T. Bailey, of the Harvard Medical School

and the Children's Hospital. These and other contributions make the first number of this journal an important addition to medical literature. The illustrations are excellent, many of them being in color. This journal, therefore, is indeed a welcome addition to medical literature, and with the fine standards set up by the initial number the editor and her editorial advisers are open to sincere congratulations.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

DONALDSON — James F. Donaldson, M.D., of Middleton, died March 10. He was in his sixty-seventh year. Dr. Donaldson received his degree from Harvard Medical School in 1902. He was a member of the Massachusetts Medical Society, the American Medical Association, and the New England Pediatric Society. His widow and three sons survive.

HARVEY — Frank T. Harvey, M.D., of Milford, died February 1. He was in his seventy-eighth year. Dr. Harvey received his degree from the New York Medical College in 1893. He was a former member of the Massachusetts Medical Society, a member of the American Medical Association and an honorary member of the staff of the Milford Hospital.

JACQUES — J. Hector Jacques, M.D., of Fitchburg, died April 15. He was in his sixty-ninth year. Dr. Jacques received his degree from Harvard Medical School in 1910. He was a member of the Massachusetts Medical Society and the American Medical Association.

LOWNEY — John F. Lowney, M.D., of Fall River, died February 19. He was in his seventy-fifth year. Dr. Lowney received his degree from Tufts College Medical School in 1900. He was elected president of the Fall River Medical Society in 1907. He was a member of the Massachusetts Medical Society and the American Medical Association. His widow survives.

MAYHEW — Orland S. Mayhew, M.D., of Vineyard Haven, died February 26. He was in his sixty-seventh year. Dr. Mayhew received his degree from Harvard Medical School in 1901. He was examining physician of the Selective Service board and chief of staff of Martha's Vineyard Hospital. He was a member of the Massachusetts Medical Society, the American Medical Association and the Martha's Vineyard Medical Society. His widow, two daughters and a son survive.

MCAUSLAN — James L. McAuslan, M.D., of North Grafton, died March 22. He was in his seventieth year. Dr. McAuslan received his degree from Harvard Medical School in 1899. He was a member of the Massachusetts Medical Society, the American Medical Association, the American Psychiatric Association and the New England Psychiatry Association. His widow, two daughters and two sons survive.

PENNY—Mary M. Penny, A.D., of Saugus, died April 11. She was in her seventy-third year. Dr. Penny received her degree from Tufts College Medical School in 1910. She founded the preschool clinic in Saugus. She was a member of the Massachusetts Medical Society, the American Medical Association and the Lynn Hospital Association. A daughter, a son, a brother and two grandsons survive.

VARNEY—Elton M. Varney, M.D., of Peabody, died April 11. He was in his sixty-sixth year. Dr. Varney received his degree from Bowdoin Medical School in 1903. He was a member of the Massachusetts Medical Society and the American Medical Association. His widow survives.

WINSLOW—George F. Winslow, M.D., of Hyde Park, died April 17. He was in his sixty-eighth year. Dr. Winslow received his degree from Harvard Medical School in 1901. After serving his internship at Carney Hospital he entered practice in Hyde Park in 1903. He was an attending physician for the Boston schools and for several district plants in Hyde Park. Dr. Winslow was a member of the Massachusetts Medical Society, the American Medical Association and the Society of Examining Physicians of Boston. His widow, a daughter, a brother and two grandchildren survive.

CIVILIAN ACTIVITIES

CIVILIAN DEFENSE

AUXILIARY EMERGENCY MEDICAL DEPOTS

The following are the requirements for retail druggists whose stores qualify as auxiliary emergency medical depots by the Committee on the Massachusetts

- The drugstore shall be approved by the committee as a suitable store for a depot.
- The drugstore shall always have on hand suitable medical supplies to care for a minimum of fifty persons who may be in need of medical supplies in time of emergency or disaster.
- The owner and his employees shall be subject to call at any hour to provide these medical supplies in the event of emergency or disaster.
- The owner shall sign an agreement that he will make available the necessary medical supplies to the Civilian Defense or Red Cross authorities when called on in the event of an emergency or disaster.
- The owner shall agree to make available these supplies whether the emergency or disaster arises out of the war or from any other accident or disaster to which the Civilian Defense or Red Cross authorities may respond.
- The owner shall comply with all the requirements and regulations promulgated or issued by the Medical Division of the Massachusetts Committee on Public Safety.
- The owner and his employees shall take orders from the chief medical officer of the community in which his store is located or from such other officer or representatives as the Medical Division of the Massachusetts Committee on Public Safety or the local chief medical officer shall designate.
- The owner and his employees shall hold themselves in readiness to co-operate and assist all duly authorized representatives of the Massachusetts Committee on Public Safety in time of emergency or disaster.
- The owner shall place in his front store window the insignia of the Auxiliary Emergency Medical Depot in accordance with the directions of the Committee on Auxiliary Emergency Medical Depots and shall not

use any other insignia or form of advertising except as approved by the Committee on Auxiliary Emergency Medical Depots.

- The owner shall surrender to the Committee on Auxiliary Emergency Depots his insignia and Civilian Defense button if in the opinion of the committee it be determined that his store is no longer a proper place to be designated as a depot.
- The owner shall attend all meetings to which he may be invited by the local medical committee of the Massachusetts Committee on Public Safety.
- The owner shall agree that all medical supplies furnished to the Civilian Defense or Red Cross authorities in time of an emergency or disaster shall be without cost to said authorities and shall be his contribution to the welfare of the community and the Commonwealth.

CORRESPONDENCE

PROCUREMENT AND ASSIGNMENT OF NURSES

To the Editor: The Procurement and Assignment Service for Nurses has two objectives: to procure the necessary nurses for the military services with due consideration for civilian needs and to bring about an equitable redistribution of nurses to maintain essential civilian nursing services.

Enlistment of nurses in the military service is voluntary, but no nurse may be accepted for military service until given a I-A classification by a committee of the Procurement and Assignment Service. By reviewing the positions of all eligible nurses the committee are making as fair a determination as possible of those best able to be declared available for military service while they are deferring those who are most essential for civilian needs.

To secure the numbers needed by the Army and Navy, a certain number of young eligible nurses will have to go from the private-duty field and general hospital, public health and industrial nursing services as well as from doctors' offices if they are doing non-nursing work or work that can be taken over without difficulty by a nurse ineligible for military service.

With the very acute shortage of physicians the essentiality of the nurse assistant to the private physician or surgeon is recognized. In order to meet our obligations and still protect all the essential civilian services however, we ask the co-operation of the doctors in two ways:

- To give the Committee of the Procurement and Assignment Service the office
- nurses so as to
- to hold nurses as
- for nursing duties and not to employ young graduates who are our most promising source of recruits for the military service.

The Army quota for 1944 has been reduced, the Navy quota remains the same. Massachusetts is asked to procure 434 nurses by July 1. The needs after that date are not known.

The response of nurses is excellent and we think that we shall be not far below our quota. We hope that we can also protect the places where the strains are most acute in civilian service owing to nursing shortage. To do so the support of the physicians is needed.

DR. ELIOT HUBBARD, JR., *Treasurer*

PROGRAM OF THE ONE HUNDRED AND SIXTY-THIRD ANNIVERSARY OF THE MASSACHUSETTS MEDICAL SOCIETY

Monday, Tuesday and Wednesday, May 22, 23 and 24, Hotel Statler, Boston

The Registration Desk will be located on the Mezzanine Floor, and all who attend the meeting are requested to register.

Owing to the lack of personnel and food supplies, the Hotel Statler must be informed concerning the number of members who will attend the various luncheons and dinners. Attendance is not limited, but tickets *must* be obtained in advance. It is doubtful whether any tickets will be available at the time of the meeting.

MONDAY EVENING, MAY 22

Annual Meeting of the Council of the Massachusetts Medical Society

- 5:00 Supervising Censors' Meeting (PARLOR D).
- 6:00 Cotting Supper (PARLORS A AND B).
- 7:00 Council — Annual Meeting (GEORGIAN ROOM).

TUESDAY MORNING, MAY 23

First General Session

GEORGIAN ROOM

Dr. George L. Schadt, *Chairman*
Dr. G. Lynde Gately, *Co-chairman*

Symposium on War Injuries

- 9:00 *Venereal Disease as a War Injury.* Dr. Oscar F. Cox, Boston. Associate professor of medicine, Boston University School of Medicine; clinical professor of urology, Tufts College Medical School; director, Division of Genitoinfectious Diseases, Massachusetts Memorial Hospitals; member, Subcommittee on Venereal Diseases, National Research Council.
- 9:20 *Surgical Experiences with Wounds in the Papaun Campaign.* Colonel Augustus Thorndike, M.C., A.U.S., Washington, D. C.
- 9:40 *Reconstructive Surgery.* Dr. Philip D. Wilson, New York. Surgeon-in-chief, Hospital for Special Surgery, New York; clinical professor of orthopedic surgery, Columbia University College of Physicians and Surgeons.
- 10:00 *Physical Therapy: Its relation to war injuries.* Dr. Kristian G. Hansson, New York. Director of physical therapy, Hospital for Special Surgery and New York Hospital.
- 10:20 *Psychiatric Casualties of the War, and Their Treatment.* Dr. Winfred Overholser, Washington, D. C. Superintendent, Saint Elizabeth's Hospital, Washington, D. C.; professor of psychiatry, Washington University School of Medicine; Chairman, Committee on Neuropsychiatry, Research Council.

11:00 Annual Meeting of the Massachusetts Medical Society

GEORGIAN ROOM

Annual Oration (following annual meeting): *The Toxic Factors in Traumatic Shock.* Dr. Joseph C. Aub, Boston. Professor of research medicine, Harvard Medical School; physician, Massachusetts General Hospital; director, Collis P. Huntington Memorial Hospital, Massachusetts General Hospital.

Annual Luncheon (PARLORS A, B, and C): tickets MUST be procured in advance of the meeting.

TUESDAY AFTERNOON, MAY 23

Second General Session

GEORGIAN ROOM

Dr. Dwight O'Hara, *Chairman*
Dr. Clifton T. Perkins, *Co-chairman*

- 2:00 *The Practitioner, the Surgeon and Endometriosis.* Dr. John Fallon, Worcester. Surgeon, Fallon Clinic.
- 2:20 *Some Practical Aspects of Female Genital Bleeding.* Dr. Richard W. Te Linde, Baltimore, Maryland. Professor of gynecology, Johns Hopkins University School of Medicine; chief gynecologist, Johns Hopkins Hospital.
- 2:40 *A Comparison of Results in Immediate and Delayed Treatment of Injured Nerves of the Forearm and Hand.* Dr. William E. Browne, Boston. Surgeon-in-chief, Second Surgical Service, Carney Hospital; clinical professor of surgery, Tufts College Medical School.
- 3:00 *Typhus.* Rear Admiral C. S. Stephenson (MC), U.S.N., Washington, D. C.
- 3:20 *Tropical Diseases of the Skin.* Dr. Howard Fox, New York. Professor of dermatology and syphilology, emeritus, New York University School of Medicine.
- 3:40 *The Study of a Patient from the Psychosomatic Standpoint.* Dr. Kenneth J. Tillotson, Belmont. Psychiatrist-in-chief, McLean Hospital, Waverley, Massachusetts.
- 4:00 *The Shattuck Lecture. A Consideration of Certain Recent Advances in Surgery.* Dr. Alfred Blalock, Baltimore, Maryland. Surgeon-in-chief, Johns Hopkins Hospital; professor of surgery, Johns Hopkins University School of Medicine.

TUESDAY EVENING, MAY 23

Annual Dinner of the Massachusetts Medical Society

GEORGIAN ROOM

Tickets for the dinner MUST be procured in advance.

Reading: Dr. Roger I. Lee, president, Massachusetts Medical Society.

Guest Speakers:

The Honorable Leverett Saltonstall, Governor of Massachusetts.

William (Bill) Cunningham, of *The Boston Herald*.

WEDNESDAY MORNING, MAY 24

Third General Session

GEORGIAN ROOM

Dr. Charles F. Wilinsky, *Chairman*

Dr. Leroy E. Parkins, *Co-chairman*

1) *Advances in Inhalation Therapy.* Dr. Maurice S. Segal, Boston. Assistant professor of medicine, Tufts College Medical School.

2) *The Apprehension of Silent and Masquerading Diseases of the Chest.* Dr. Norman J. Wilson, Boston. Assistant in surgery, New England Deaconess Hospital.

3) *Practical Consideration in the Diagnosis and Treatment of Infantile Paralysis.* Dr. William T. Green, Boston. Director of clinics, Harvard Infantile Commission.

4) *The Rehabilitation of Returned Veterans in Industry.* Dr. Frederic N. Manley, Quincy. Chief surgeon, Bethlehem Steel Corporation, Shipbuilding Division, Boston Area; associate professor of industrial medicine, Tufts College Medical School.

5) *Postwar Planning in Anesthesiology.* Dr. Henry S. Ruth, Philadelphia. Professor and chief of the Section of Anesthesiology, Hahnemann Medical College and Hospital, Philadelphia.

Symposium on Gall-Bladder Disease

6) *Medical View of Gall-Bladder Disease.* Dr. Walter C. Alvarez, Rochester, Minnesota. Professor of medicine, University of Minnesota (Mayo Foundation); consultant, Division of Medicine, Mayo Clinic.

7) *Surgical Aspects of Gall-Bladder Disease.* Dr. Howard M. Clute, Boston. Professor of surgery, Boston University School of Medicine; surgeon-in-chief, Massachusetts Memorial Hospitals; surgeon, New England Baptist Hospital.

8) *Radiologic Aspects of Gall-Bladder Disease.* Dr. Merrill C. Sosman, Boston. Roentgenologist, Peter Bent Brigham Hospital; clinical professor of roentgenology, Harvard Medical School.

9) *Question-and-Answer Period on Gall-Bladder Disease*

WEDNESDAY NOON, MAY 24

Section Meetings and Luncheons

12:00 m.-2:00 p.m.

Tickets for the luncheon MUST be procured in advance.

Section of Medicine

PARLOR B, HOTEL STATLER

Dr. George D. Henderson, Holyoke, *Chairman*

Dr. Albert A. Hornor, Boston, *Secretary*

Abdominal Pain. Dr. Walter C. Alvarez, Rochester, Minnesota. Professor of medicine, University of Minnesota; consultant, Division of Medicine, Mayo Clinic.

Section of Surgery

PARLOR C, HOTEL STATLER

Dr. Howard M. Clute, Boston, *Chairman*

Dr. Charles F. Twomey, East Lynn, *Secretary*

How Shall We Provide Postgraduate Training in Surgery for Men at Present Serving in the Armed Forces? Dr. Allen O. Whipple, New York. Professor of surgery, Columbia University College of Physicians and Surgeons; director of the Surgical Service, Presbyterian Hospital, New York.

Section of Pediatrics

THE JUNIOR LEAGUE, ZERO MARLBOROUGH STREET

Dr. Leroy T. Stokes, Haverhill, *Chairman*

Dr. Gerald N. Hoeffel, Cambridge and Boston, *Secretary*

Therapy of Anemias in Childhood. Dr. Louis K. Diamond, Boston. Assistant professor of pediatrics, Harvard Medical School; visiting physician, Children's and Infants' hospitals.

Section of Obstetrics and Gynecology

PARLOR A, HOTEL STATLER

Dr. Christopher J. Duncan, Brookline, *Chairman*

Dr. F. G. Edgelow, Springfield, *Vice-chairman*

Dr. George Van S. Smith, Brookline, *Secretary*

Dysmenorrhea: Its cause and treatment. Dr. Frank A. Pemberton, Boston, Dr. George Van S. Smith, Boston, and Dr. Louis E. Phaneuf, Boston.

Section of Radiology

FOURTH FLOOR, HOTEL STATLER

Dr. Stanley A. Wilson, Salem, *Chairman*

Dr. George Levene, Chestnut Hill and Boston, *Secretary*

Uterine Bleeding. Dr. Joe V. Meigs, Boston.

Section of Physiotherapy

FOURTH FLOOR, HOTEL STATLER

Dr. Wilmot L. Marden, Boston and Lynn, *Chairman*

Dr. Howard Moore, Newton and Boston, *Secretary*

Occupational Therapy for War Wounded and Physical Medicine in Army Practice. Captain Sidney Licht, U.S.A. Chief physical therapist, Lovell

Section of Dermatology and Syphilology

HANCOCK ROOM, HOTEL STATLER

Dr. John G. Downing, Newton and Boston, *Chairman*Dr. G. Marshall Crawford, Lincoln and Brookline, *Secretary*

Pinta. Dr. Howard Fox, New York. Professor of dermatology and syphilology, emeritus, New York University College of Medicine.

MASSACHUSETTS MEMBERS OF THE NEW ENGLAND SOCIETY OF ANESTHESIOLOGY

PARLORS D AND E, HOTEL STATLER

Anesthesia: A general discussion. Dr. Henry S. Ruth, Philadelphia. Professor and chief of the Section of Anesthesiology, Hahnemann Medical College and Hospital, Philadelphia.

WEDNESDAY AFTERNOON, MAY 24

Fourth General Session

GEORGIAN ROOM

Dr. Daniel B. Reardon, *Chairman*Dr. Vlado A. Getting, *Co-chairman*

2:00 *The Goal of an Eye-Hygiene Program for School Children.* Dr. James J. Regan, Boston. Ophthalmic surgeon-in-chief, Boston City Hospital; assistant professor of ophthalmology, Tufts College Medical School.

2:20 *Differential Diagnosis of Weakness and Fatigue.* Dr. Frank N. Allan, Boston. Co-director, Department of Internal Medicine, Lahey Clinic.

2:40 *The Prevention of Pulmonary Embolism.* Dr. Charles A. Robinson, Boston. Junior visiting surgeon, First Surgical Service, Carney Hospital; chief of Varicose Vein Clinic, Carney Hospital.

3:00 *Clinical Importance of the Rh Blood Type.* Dr. Louis K. Diamond, Boston. Assistant professor of pediatrics, Harvard Medical School; visiting physician, Children's and Infants' hospitals.

3:20 *Review of McMurray Osteotomies for Ununited Hip Fractures.* Dr. Otto J. Hermann, Boston. Clinical professor of surgery, Tufts College Medical School; associate in surgery, Harvard Medical School; surgeon-in-chief, Bone and Joint Service, Boston City Hospital.

3:40 *Nutrition in Postwar Rehabilitation.* Dr. Fredrick J. Stare, Boston. Assistant professor of nutrition, Harvard Medical School and School of Public Health; junior associate in medicine, Peter Bent Brigham Hospital.

4:00 *Panel Discussion: The selection and use of the newer drugs.* Dr. Chester S. Keefer, *Chairman*. Director, Evans Memorial Hospital; physician-in-chief, Massachusetts Memorial Hospitals; Wade Professor of Medicine, Boston University School of Medicine.

Discussers:

Dr. Charles A. Janeway. Assistant professor pediatrics, Harvard Medical School and School of Public Health; visiting physician, Children and Infants' hospitals.

Dr. Maxwell Finland. Assistant professor of medicine, Harvard Medical School; associate physician, Thorndike Memorial Laboratory; chief, Fourth (Harvard) Medical Service, Boston City Hospital.

Dr. Donald G. Anderson. Research fellow in medicine, Evans Memorial Hospital; instructor in medicine, Boston University School of Medicine.

Scientific Exhibits

BALLROOM ASSEMBLY

Booth
S-13-16

Anesthesia. Massachusetts members of the New England Society of Anesthesiology. Exhibitors: Boston City Hospital, Massachusetts General Hospital, Massachusetts Memorial Hospitals and Lahey Clinic (Dr. U. Eversole, Dr. L. V. Hand and Dr. M. Nicholson).

S-17

Weakness and Fatigue. Lahey Clinic. Exhibitor: Dr. Frank N. Allan.

S-18

Occupational Disease Prevention. Massachusetts Division of Occupational Hygiene.

S-19-20-21

Malaria Control. Massachusetts Department of Public Health and Massachusetts Reclamation Board.

S-22

Veneral Disease Control. Massachusetts Department of Public Health.

S-23

Fractures. Massachusetts Committee on Fractures and Trauma, American College of Surgeons. Demonstration of first aid members of the American Red Cross Metropolitan Chapter, Boston and Newton chapters.

S-24

Modern Pharmacy. Massachusetts State Pharmaceutical Association.

S-25-26

The Health Department Serves the Physician. The Health Department, City of Boston.

S-27

Blood for Victory. Blood Donor Centre, Boston Metropolitan Chapter, American Red Cross.

S-28

Industrial Dermatitis. The Department of Dermatology, Boston University School of Medicine. Exhibitor: Dr. F. Ronchese.

S-29

Absenteeism. The Committee on Industrial Health. Exhibitor: Dr. Daniel L. Lynch.

S-30

Cancer of the Larynx. Dr. L. A. Schall.

S-31

X-ray Finds Tuberculosis Early — Listen! Finds It Late. Massachusetts Tuberculosis League.

S-32

The Answer to Socialized Medicine. The Blue Cross and the Blue Shield.

MEZZANINE

- (1) *Penicillin and Results of Therapy with this Agent.* (2) *Model of Rehabilitation Work-shop, and Management of Battle Casualties.* (3) *Tropical Diseases: Its problems here and in the South Pacific.* (4) *The Control of Streptococcal Infection.* Medical departments, United States Army, First Service Command, and the United States Navy, First Naval District.

Motion Picture Program

LOWER LOBBY

Tuesday, May 23

- 9:45 *Inguinal Hernia.*
 10:00 *Surgical Pathology of the Appendix.*
 10:15 *Surgical Pathology of the Breast.*
 10:45 *Cancer of the Female Breast.*
 1:15 *Treatment of Normal Breech Presentation.*
 1:40 *Continuous Gaudal Analgesia.*
 2:00 *Transverse Cervical Cesarean Section.*
 2:40 *Combined Abdominoperineal Resection of the Rectum (Miles Technic).*
 3:00 *First-Stage Thoracoplasty for Pulmonary Tuberculosis.*
 3:15 *Second-Stage Thoracoplasty for Pulmonary Tuberculosis.*
 3:30 *Nephrectomy for Tuberculosis of the Kidney.*
 4:00 *Fusion of Lumbosacral Joint and Hemilaminectomy for Removal of Herniated Disk.*
 4:20 *Surgical Anatomy of the Hand.*
 4:40 *Correction of Nasal Deformities.*

Wednesday, May 24

- 10:00 *Subtotal Thyroidectomy for Primary Hyperthyroidism.*
 10:15 *Open Reduction of Fracture of Neck of Femur.*
 10:30 *Use of the Miller-Abbott Tube.*
 11:00 *Skin Grafting of War Wounds.*
 11:30 *Treatment of War Burns of the Hand.*
 12:00 *Immunization Against Infectious Diseases.*
 2:30 *Subtotal Gastrectomy for Perforating Duodenal Ulcer.*
 2:45 *Ileostomy for Ulcerative Colitis.*
 3:00 *Hemorrhoids and a Method of Hemorrhoidectomy.*
 3:30 *Abdominal Complete Hysterectomy for Fibroids.*
 4:00 *Vaginal Repair of Cystocele and Rectocele.*
 4:15 *Radical Operation for Carcinoma of Prostate.*
 4:30 *Repair of Burn Contractures of the Neck.*
 4:50 *Reconstruction of Nose.*

AMERICAN COLLEGE OF SURGEONS

A meeting of the Regional Fracture Committee of Massachusetts of the American College of Surgeons will be held in Parlor C of the Hotel Statler at 2:00 p.m., Wednesday, May 24.

MASSACHUSETTS MEDICO-LEGAL SOCIETY

A meeting of the Massachusetts Medico-Legal Society will be held on the fourth floor of the Hotel Statler at 2:00 p.m., Tuesday, May 23 (the room number can be obtained at the Information Desk, Hotel Statler).

BOOK REVIEWS

Proteins, Amino Acids and Peptides as Ions and Dipolar Ions. By Edwin J. Cohn, Ph.D., and John T. Edsall, M.D. 8°, cloth, 686 pp., with tables and charts. New York: Reinhold Publishing Corporation, 1943. \$13.50.

The authors attest, in their preface, the significance of the purely physicochemical work of Debye and Hückel and of Bjerrum in the development of knowledge of protein chemistry since 1923. The book as a whole summarizes the experimental and mathematical approaches whereby the size and shape of protein molecules have been determined. In gaining this end, the authors include full discussions of many related physical properties of proteins, amino acids and other ion-dipoles. Such properties include viscosity, solubility, distribution of charges and the like. A chapter on the amino acid composition of proteins is included. Although full consideration is given to all significant advances in this particular field, the book is of particular value for its exposition of certain special methods, some of which have reached their fullest development in the authors' laboratories; such methods include measurements of dipole moments and of double refraction of flow. It appears to the reviewer to be the most outstanding monograph on this particular subject since the publication of Jacques Loeb's classic. The style is scholarly and richly mathematical, with no attempt at popularization and with no discussion of the many possible medical and technological applications of the material presented.

An Introduction to Clinical Perimetry. By H. M. Traquair, M.D., F.R.C.S. (Edin.). With a foreword by Norman M. Dott, M.B., Ch.B., F.R.C.S. (Edin.). Fourth edition, revised and enlarged. 8°, cloth, 332 pp., with 245 illustrations and 3 coloured plates. London: Henry Kimpton, 1942. \$6.50.

Traquair's fourth edition constitutes an authoritative and indispensable guide to ophthalmologists, neurologists and neurosurgeons for an understanding, both qualitative and quantitative, of the visuosensory mechanism, and thus for adequate localization and follow-up of lesions affecting the visual pathways from the retina to the visual cortex.

Excellent clinical judgment, which can grow only from extensive and discerning experience, speaks out from each page of the text. Lucid writing, well-chosen illustrations, nearly five hundred references to the literature, and an ample index of authors and titles combine to make this volume most useful to the practitioner working in the overlapping fields of ophthalmology and neurology. Indeed, the best interests of the patient are not served unless the practitioner understands and applies the principles that are so well outlined in this text, and applies them early in the study of the patient.

In the past, perimetric and tangent screen examinations have too often been postponed until gross defects have appeared in the visual fields. Now, early localization of lesions of the visuosensory pathways should be the aim of every practitioner, either through acquiring skill in perimetry on his own account or through the addition of a skilled perimetrist to his staff. Adequate perimetry requires time, patience, understanding and intelligent co-operation on the part of the patient, a bilateral game that permits no "short-cuts."

This book clearly points the way to more effective practice. Let it be hoped that every first-class ophthalmologist and neurologist will avail himself of this help.

A Handbook of Psychiatry. By P. M. Lichtenstein, M.D., LL.B., and S. M. Small, M.D. 8°, cloth, 330 pp. New York: W. W. Norton & Company, Inc., 1943. \$3.50.

This book is rather unusual. It is excellently written and covers the field of psychiatry, with up-to-date references to the literature. The aim of the book is not to provide a text for the teaching of psychiatry or for a book to supply the needs of the general practitioner. It is intended for those who have charge of psychiatric cases in hospitals, particularly nurses and social workers, and also for the representatives of the law who have to deal with mental problems regarding commitment in the commission of crime. In the reviewer's opinion, this is a sound book and should be extremely helpful to any intelligent layman, such as an officer of the law who had to deal with psychiatric problems.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

The Modern Management of Colitis. By J. Arnold Bargen, M.D., chief of the Section on Intestinal Diseases, Division of Medicine, Mayo Clinic, and associate professor of medicine, Mayo Foundation, Rochester, Minnesota. 8°, cloth, 322 pp., with 148 illustrations. Springfield, Illinois: Charles C Thomas, 1943. \$7.00.

This special monograph is based mainly on the author's observations and experiments at the Mayo Clinic. The classification of the types of ulcerative colitis has been made and recorded in this volume.

The Johns Hopkins Hospital and The Johns Hopkins University School of Medicine: A chronicle. Volume I. Early years, 1867-1893. By Alan M. Chesney, M.D., associate professor of medicine and dean of the medical faculty, Johns Hopkins University School of Medicine. With a foreword by William H. Howell, Ph.D. 8°, cloth, 318 pp., with 36 illustrations and frontispiece. Baltimore: The Johns Hopkins Press, 1943. \$3.00.

This history brings out clearly the relations between the school and the hospital that have existed from the beginnings of these two institutions. It covers the period when Drs. Welch, Osler, Halstead and Kelly were active in the hospital.

Psychological Medicine: A short introduction to psychiatry. With an appendix, "War-Time Psychiatry." By Desmond Curran, M.B., F.R.C.P., D.P.M., psychiatrist and lecturer in psychological medicine, St. George's Hospital, and honorary psychiatrist to the Maida Vale Hospital for Nervous Diseases, London; and Eric Guttman, M.D., L.R.C.P.Ed., neuropsychiatric specialist, Emergency Medical Service. With a foreword by J. J. Conybeare, D.M. (Oxon), physician to Guy's Hospital, London. 8°, cloth, 188 pp., with 21 illustrations. Baltimore: The Williams and Wilkins Company, 1943. \$3.50.

This short manual on psychiatry includes the experience of the present war period that has brought to light great numbers of psychiatric patients in the services and on the home front. The appendix on wartime psychiatry should be of great value to medical officers in the armed services.

NOTICES

GREATER BOSTON MEDICAL SOCIETY

A meeting of the Greater Boston Medical Society will be held in the auditorium of the Beth Israel Hospital on Friday, May 12, at 8:30 p.m. Dr. Joseph E. F. Riscman will show a motion picture entitled "Angina Pectoris," in color and sound. A discussion by Dr. Samuel Levine will follow.

MENINGOENCEPHALITIS IN LYMPHOGRANULOMA VENEREUM*

A Report of Two Cases

LIEUTENANT CHRIS J. D. ZARAFONETIS, M.C., A.U.S.

WASHINGTON, D.C.

LYMPHOGRANULOMA VENEREUM has been extensively studied since 1913, when first in the disease received added impetus from the report of Durand, Nicolas and Favre.¹ In the recent years evidence has accumulated tending to emphasize the concept that this virus infection is not a localized disease but is in reality a systemic infection.²⁻⁵ Besides the more frequent involvement of the genitals and regional lymph nodes, with or without rectal stricture as a sequela, in Rooyen² has listed the following ways in which lymphogranuloma venereum may manifest itself: involvement of the throat, with inflammation of the tonsils, ulceration or angina; fever, with headache and other pyrexial disturbances; skin rashes; various forms of articular involvement; generalized involvement of the lymph nodes, with splenomegaly and hepatomegaly; granulomatous conjunctivitis; epididymitis; and meningoencephalitis. Harrop et al.^{4,5} have extended the clinical knowledge of this virus disease by a description of 3 cases occurring in laboratory workers. In these patients the infection was associated with a septic type of fever, chills and sweats, articular rheumatism, headache and, in 2 cases, cervical lymphadenitis. In the last-named cases, the authors were of the opinion that the patients were infected via the upper respiratory tract, and noted that lymphogranuloma venereum can occur as an acute infection without apparent localization and tissue reaction at the point of invasion.

Of increasing interest has been the demonstration of involvement of the central nervous system by lymphogranuloma venereum. Findlay⁷ demonstrated changes characteristic of meningoencephalitis in monkeys, mice, guinea pigs, rabbits and dogs following intracerebral inoculation with the virus. Although the occurrence of severe headaches in human cases was long known, its importance was not sufficiently stressed until von Haam and Aunoy³ published their studies in 1936. They isolated the virus from the spinal fluid of 2 patients dur-

ing the acute stage of infection, thereby incriminating the agent when the cerebral manifestations consisted mainly of headache. During the same year, Rajam⁸ reported a clinically diagnosed case of lymphogranuloma venereum in which there had been surgical interference with the inguinal buboes. This was followed by an acute exacerbation of the illness, with manifestations of severe meningoencephalitis and death. Sabin and Aring⁶ recently published evidence that more definitely established this agent as a cause of severe meningoencephalitis in man. On two occasions they isolated the virus from the spinal fluid of a patient showing marked cerebral changes. The virus was also obtained from an inguinal lymph node six weeks after the onset of the acute phase of illness and from a penile wart. Further proof of the etiologic relation of the virus to the illness encountered was found in complement-fixation studies.

In the present paper additional evidence is submitted that lymphogranuloma venereum may be a cause of acute meningoencephalitis. The first case described offers several other clinical features of interest. These include the isolation of the virus from an inguinal lymph node some five months after the onset of illness, the spinal block encountered, the striking spinal-fluid findings and the results of Frei tests and complement-fixation tests with a variety of antigens. In addition, the isolation of the virus and the experiments leading to its identification are detailed.

A second case of meningoencephalitis probably due to lymphogranuloma venereum is briefly described.

CASE REPORTS

CASE 1. L. B. A., a 24-year-old Negro private, was admitted to the State Hospital for the Insane, Philadelphia, on October 1, 1943. The date of onset of illness was approximately September 1, 1943. The patient recovered to be questioned, however, the patient stated that he had been in excellent health until the latter part of September, when he first noted the formation of a "knot" about the size of an almond in the right inguinal region. This was followed in a few days by the appearance of a grayish, watery urethral discharge without associated burning or irritation. The

*From the Division of Virus and Rickettsial Diseases, Army Medical School, Washington, D.C.

patient's last exposure to venereal disease had occurred 4 weeks prior to the appearance of the discharge, with previous exposures at 2-week intervals to the same person.

At that time the patient was transferred from Camp Gordon, Georgia, to Indiantown Gap and, while en route, experienced chilly sensations, weakness and severe bi-frontal and occipital headache. After arriving at his new post, he went to the Dispensary regularly because of the severe headache. Since his temperature was found to be mildly elevated, he was given analgesics, with little relief. On his calling attention to the urethral discharge, he was given sulfonamide tablets, of which he took 6 daily for one week. This lessened the amount of urethral discharge but did not stop it.

On October 10, still troubled with weakness, chills, feverishness and severe headaches, the patient went A.W.O.L. to visit his home in Texas. There he continued to be ill and was advised by a physician to return to camp. While on the train

There were 541 white cells per cubic millimeter, with 20 per cent polymorphonuclear leukocytes and 80 per cent lymphocytes. The globulin reaction was markedly positive.

Mental clearing continued, with a gradual improvement of the memory. The patient had no recollection of events for 5 days beginning on October 24. He complained of blurring of vision and diplopia and persistent headache. By November 6, the stiffness of the neck had decreased and a lumbar puncture again gave signs of block. Marked weakness and pains in the extremities were prominent complaints. Although there was slow, steady general improvement, the patient was transferred on December 12 to the Walter Reed General Hospital in Washington, D. C., because of the persisting spinal block.

At that time the patient did not appear very ill, was well oriented and displayed no mental aberrations. He complained of generalized weakness and headaches. Examination revealed weakness of all four extremities, more marked in the proximal musculature. He was unable to lift his arms and

back to camp on October 24, he vomited twice and was extremely drowsy. He fell asleep, and there followed a period of amnesia lasting for 5 days. He was taken to the Marine Hospital in Pittsburgh and transferred to the Station Hospital at Indiantown Gap on the same day.

Physical examination at that time showed a temperature of 101°F., a pulse of 70 and respirations of 20. The patient was disoriented and confused, and complained of headache and stiffness of the neck. The pupils were equal, reacted to light and were in accommodation. Extraocular movements appeared normal, as were the eyegrounds. There was marked nuchal rigidity. The other positive findings included lower abdominal tenderness, an enlarged and tender right inguinal lymph node, a urethral discharge and positive Kernig and Brudzinski signs. All the reflexes were active and equal, and there were no motor or sensory changes.

The red-cell count was 4,850,000, and the hemoglobin 90 per cent. The white-cell count was 18,400, with 72 per cent neutrophils, 26 per cent lymphocytes and 2 per cent monocytes. The urine was normal. Smears of the urethral discharge revealed many pus cells but no gram-negative intracellular diplococci. A blood Kahn test made on October 29 was doubtful but negative on the following day. A blood culture was negative after 7 days.

Spinal-fluid examination on October 26 revealed the initial pressure to be equivalent to 380 mm. of water (Table 1). Abdominal compression caused a prompt rise in pressure, but there was no increase with jugular compression. The fluid was slightly cloudy, with 612 red cells and 11 white cells per cubic millimeter. The globulin reaction was +++++. Smears of the fluid, as well as those of all subsequent fluids, were negative for organisms, and cultures showed no growth. Roentgenologic examination of the chest and skull failed to reveal any significant pathologic change.

The temperature gradually returned to normal over a period of 7 days, the pulse rate increasing as the temperature declined. The patient's confusion became much less and he appeared less toxic. The signs of meningeal irritation, however, persisted as severely as before. A second lumbar puncture on October 28 showed that the pressure was elevated and again gave signs of block. The fluid was xanthochromic.

thighs off the bed, but had a fair grip in the hands and fairly strong movement of the toes and feet. The musculature of the extremities was flabby, but fibrillations were not present. The deep tendon reflexes were uniformly hypoactive, whereas abdominal reflexes were absent. To all forms of sensation there was a glove-and-stocking type of hypesthesia, extending to the level of the wrists and to the junction of the middle and lower thirds of the legs.

A lumbar puncture on December 13 showed no change in the fluid dynamics. Neck compression by means of a cuff at 40 mm. of mercury elicited no response. The fluid contained 8 lymphocytes per cubic millimeter and a total protein of 2590 mg. per 100 cc., and the colloidal-gold curve was 5555555555. Wassermann tests, as well as Kline diagnostic and inclusion tests and Kolmer complement-fixation tests, on this and all subsequent spinal fluids were negative.

Slow but steady improvement followed, although therapy was nonspecific. Late in December, lymphogranuloma venereum was first suspected as the causative agent. A Frei test was done, using antigen of chick-embryo origin, but was negative. This was repeated on January 10, 1943, and was again negative. The spinal fluid was examined on the following day, with essentially no change from the preceding findings. At that time the colloidal-gold curve in a 20-tube test was 5555555555, 5555432000. Mice were inoculated intracerebrally and intraperitoneally with portions of this spinal fluid, but no virus was isolated. Complement-fixation tests on serum obtained on January 15 were strongly positive for the lymphogranuloma-psittacosis group (Table 2). Further Frei tests were carried out, using both chick-embryo and human antigens, the former yielding a questionably positive result, whereas the latter was negative (Table 3).

By that time the patient had improved sufficiently to be able to walk around, but still complained almost daily of bi-frontal and occipital headache. There was also pain in the cervical region and upper dorsal spine. This pain was made worse by sudden acute flexion or extension of the head.

On February 22, the single enlarged right inguinal lymph node was surgically removed and half of it sent to the Virus Laboratory of the Army Medical School. From it a virus was isolated and identified as that of lymphogranuloma

venereum. Therefore, beginning on March 3 and continuing through March 26, the patient was given 5 gm of sulfathiazole daily. A few days prior to the institution of this therapy the urethral discharge had spontaneously ceased. A further attempt was made to isolate virus from the spinal

fluid drawn on March 11, but it was unsuccessful. It should however be noted that the sulfathiazole level of this specimen was 0.85 mg per 100 cc.

By April 9 the patient was feeling much stronger with only mild weakness of the extremities and the sensory deficit had disappeared. Headache was still present but was not so

Fifteen urine examinations were essentially negative. Urethral smears were repeatedly examined for gram negative intracellular diplococci, but all were negative. Three urethral cultures for gonococci were negative.

Routine x ray examinations of the skull, chest and cervical spine were negative as were special roentgenologic studies of the cervical and dorsal spine and the skull.

December 24 showed a leukocyte count of 8 per second. The leukocyte count was from 9 to 9.5 per second on March 8 and about 10 per second on March 30. In each test there was a marked build up with overventilation, with a slow return to the resting state.

The final clinical diagnosis was myelomeningoencephalitis with adhesive arachnoiditis secondary to lymphogranuloma venereum.

CASE 2. L. B., a 22 year old Negro private was admitted to the Station Hospital at Fort Bragg, North Carolina, on July 30 1941. He gave a history of having had coitus without prophylaxis on July 7. Swelling and tenderness appeared in the right inguinal region on July 15 and progressed to the time of admission.

Physical examination was negative except for the painful and tender right inguinal adenitis. The urine was normal.

On August 7, the red cell count was 4,930,000 and the white cell count 14,600. A lumbar puncture on August 7 revealed the spinal fluid to be under slightly increased pressure. There were 483 white cells per cubic millimeter, with 75 per cent lymphocytes and 25 per cent polymorphonuclear

At that time the spinal block was still present. In addition Frei tests with Lygranum S T and other yolk sac antigens were positive.

Other findings were as follows:

Sixteen c normal ran white cell (100 with 72 per cent neutrophils and 26 per cent lymphocytes. Subsequent counts ranged from 5800 to 11,500, with an essentially normal differential except for a mild degree of eosinophilia (3 to 9 per cent). On February 21, 1943 the clotting time was 4 minutes and the bleeding time 2 minutes. The sedimentation rates in three determinations made over a 4-month period were 20, 20 and 17 mm per hour. A blood culture taken during the acute febrile phase of the illness showed no growth after 7 days. A doubtful Kahn test was obtained from the serum of October 28, but all subsequent tests were negative. Complement fixation tests for meningococcus, streptococcus, diphtheria, tetanus, Eastern equine encephalitis negative.

An intradermal tuberculin test made on May 27, 1943 with 0.00002 mg PPD (purified protein derivative) was negative, or one made with 0.005 mg PPD on June 4 was positive.

Blood chemistry studies made on December 15 1942 showed the sugar level to be 114 mg per 100 cc and the urea level 9 mg. On December 8, the total protein determination was 7.84 gm per 100 cc with 4.57 gm of albumin and 3.27 gm of globulin per 100 cc. On April 8 1943, the total protein was 9.0 gm, with 4.82 gm of albumin and 4.18 gm of globulin.

leukocytes. Smears showed no organisms and cultures were negative. On August 11 a Frei test was positive.

On August 4 the patient developed frontal and occipital headache and photophobia. This persisted for the next 3 days and then subsided. The temperature during that time was between 100 and 101°F.

A clinical diagnosis of meningoencephalitis secondary to lymphogranuloma venereum was made.

Serum taken from the patient on August 16 and stored at -20°C was tested 21 months later and gave a positive complement fixation reaction for lymphogranuloma venereum in dilutions up to 1:64 (Table 2).

VIRUS STUDIES

Although in Case 1 an association between the findings in the central nervous system and lymphogranuloma venereum was suggested by the positive complement-fixation tests, it was thought that isolation of the virus would offer more conclusive evidence of such a relation. Accordingly, efforts were made to isolate virus, even though a considerable interval had elapsed after the acute febrile phase of the illness. These studies are described below.

Cerebrospinal fluid. Bacteriologically sterile specimens of spinal fluid were obtained on January 11 and March 11, 1943, for attempts at isolation of virus. Mice were inoculated intracerebrally and intraperitoneally with 0.03 cc. and 0.1 cc of the fluid, respectively. None of these animals showed clinical evidence of disease. Several passages were

made in an effort to bring out possible unapparent infection, but without success. All the mice not sacrificed for passage were tested intracerebrally for immunity to lymphogranuloma venereum virus, and were found to be nonimmune.

Lymph node. The right inguinal lymph node noted in the clinical record was removed on February 22, about five months after it had appeared. Grossly, it measured 15 by 10 by 7 mm. and was grayish-white, with a slightly nodular surface. It was sectioned with ease, revealing a 3-mm. rim of lymphoid tissue supported on fatty tissue. Half the node was reserved for virus study and the remainder was fixed for pathological study. Sections of this material were studied at the Army Medical Museum, where the following description was made:

The lymph node is the seat of low-grade chronic inflammation of nonspecific character as judged by the histopathologic appearances. The capsule is thickened and infiltrated by lymphocytes and plasmocytes, and the trabecular and hilar connective tissue is increased in amount. The follicles are hypertrophied and there is considerable mitotic activity in the germinal centers. The lymphoid and reticuloendothelial elements of the node are hyperplastic, and the latter are actively phagocytic, containing nuclear debris and occasional brown pigment resembling melanin. There is no suggestion of the tubercloid lesions of lymphopathia venereum. Diagnosis: chronic hyperplastic lymphadenitis, nonspecific.

At the Virus Laboratory, smears were made from the cut surface of the lymph node and stained by the Macchiavello technic. Several minute red bodies resembling the elementary bodies of lymphogranuloma venereum were observed. Blood agar cultures of this material were negative. A portion of the node was ground, suspended in saline solution and injected intracerebrally and intraperitoneally (0.03 cc. and 0.2 cc. of a 10 per cent suspension, respectively) into 6 mice. One mouse appeared ill on the fourth day and was sacrificed. A 10 per cent suspension of the brain was injected intracerebrally into other mice. Cultures of the inoculum were negative. Three more of the original 6 mice showed signs of illness from which they slowly recovered, but the 2 remaining mice failed to become ill.

All the second-passages mice showed evidence of disease four to six days following inoculation. Macchiavello-stained touch smears of the meninges revealed elementary bodies of the lymphogranuloma venereum type, whereas bacteriologic cultures were negative. The virus* was maintained by intracerebral passage in mice.

Characteristics of the Virus

Mice. The L. A. virus was carried through thirteen successive mouse passages before being stored at -70°C . In these animals, following intracerebral inoculation the disease was characterized by roughening of the fur, hunching and weight loss. Frequently, the first sign of illness was that of

hyperactivity induced by tactile stimuli, often ending in a tetanic convulsive seizure, with or without death ensuing at that time. Not infrequently, mice passed through this phase of hyper-reactivity into a longer period of apathy, with hunched backs, roughened coats and emaciation. In two or three weeks gradual improvement followed, with apparent clinical recovery. Such mice were usually immune to subsequent reinoculation with the virus.

Brain material from the fourth mouse passage was titrated intracerebrally in mice. Half the mice died in each tenfold dilution through 1:10,000. The remaining mice became sick through dilutions of 1:1,000,000 and then slowly recovered.

Intraperitoneal inoculation with 0.1 to 0.2 cc. of a 10 per cent suspension of fresh infected mouse-brain material did not give rise to clinical disease. Three or four such injections at intervals of a few days to a week usually resulted in immunity to intracerebral inoculation with the homologous strain.

Guinea pigs. Two adult male guinea pigs were inoculated with a 10 per cent suspension of infectious brain material from the third mouse passage, each receiving 0.1 cc. intradermally and 1.0 cc. subcutaneously in the inguinal region. Both animals developed moderate fever — one from the second to the fourth day, the other on the fifth and sixth days. Inguinal adenopathy appeared in one animal, which also developed a vesiculopustular lesion at the site of intracutaneous injection. A red papular lesion was produced in the other animal. Both skin lesions gradually subsided in a few days.

Developing chick embryos. A bacteriologically sterile 10 per cent suspension of infectious brain material from the second mouse passage was inoculated in 0.2-cc. amounts onto the chorioallantois of ten-day developing chick embryos. By the fifth day, central plaque lesions and numerous secondary pocklike foci appeared in about half the eggs. These lesions were usually whitish and opaque, but occasionally clear vesicles were produced. Smears stained by Macchiavello's method showed occasional elementary bodies and plaques. One of the infected membranes was ground into a 10 per cent suspension, and other embryonated eggs were inoculated. Ten-day embryos received 0.2 cc. on the chorioallantois, whereas six-day embryos had 0.5 cc. injected into the yolk sac. About half those inoculated on the chorioallantoic membrane developed lesions. This type of passage was then discontinued.

Of 6 embryos inoculated in the yolk sac, only 1 was heavily infected when examined ten days after injection. This yolk sac was ground, a 1:10 suspension was made, and 0.5 cc. was inoculated into the yolk sac of additional six-day embryos. The L. A. virus was carried through thirteen successive yolk-sac passages before being stored at -70°C . During this series of passages, the best yield of elementary bodies resulted when seven-day or eight-day embryos were inoculated with 0.5 cc. of a 1:50 dilution

*The virus isolated from Case 1 is referred to throughout as the "L. A. virus."

of infected yolk-sac material. Such embryos usually died four to six days after inoculation.

Studies to Establish the Identity of the Virus

The manifestations of infection with L. A. virus in the mice, guinea pigs and developing chick embryos were consistent with those described by others^{2,7,9-11} for lymphogranuloma venereum. In addition, parallel infection experiments with a known strain of lymphogranuloma venereum virus were carried out in mice (five passages) and chick embryos (thirteen yolk-sac passages), with essentially identical findings.

The pathologic changes induced in mice intracerebrally inoculated with the L. A. virus were also comparable with those known to occur in these animals when infected with lymphogranuloma venereum.⁷ Polymorphonuclear and round-cell infiltration of the meninges was the most striking feature. Although perivascular cuffing of moderate degree was observed, the involvement of the brain substance was minimal.

Further information concerning the identity of the L. A. virus was obtained from cross-immunity tests in mice. The animals were immunized to the virus by repeated intraperitoneal injections* of infectious mouse-brain suspensions. Inoculations were made at intervals of a few days to a week or more, a total of four or five injections of 0.1-cc. amounts being made before a final intracerebral inoculation was made with the homologous virus. Similarly, mice were immunized to a known strain of lymphogranuloma venereum virus. The injected mice were then tested intracerebrally with 0.03 of a fresh 10 or 20 per cent suspension of infectious mouse-brain material of the

antigen made from the virus isolated from the patient and hence labeled "L. A. antigen." Lygranum C. F. is a commercial preparation (Squibb) from yolk-sac material infected with lymphogranuloma venereum virus. It has been used extensively in complement-fixation tests for this disease.^{6, 13, 14} The other two antigens were also prepared from infected yolk-sac material using an ether-extraction method. This technique has been applied to the lymphogranuloma-psittacosis group of viruses by several workers.¹⁵⁻¹⁷ Only those yolk sacs that appeared rich in elementary bodies were used in the preparation of the L. A. antigen. Before inactivation of the material, it was titrated intracerebrally in mice. It was found to make all the mice definitely ill in ten-fold dilutions through 1:100,000; however, deaths were few and were distributed unevenly in the various dilutions.

Frei Tests

The above laboratory data indicated that the patient had had active lymphogranuloma venereum infection for at least six months. During that period, however, four Frei tests had been made, with only one questionably positive result (Table 3). A new series of Frei tests was therefore carried out, using antigens of chick-embryo origin.^{12, 18} These antigens included the commercial product (Lygranum S. T.); the Frei antigen of the Army Medical School and the L. A. antigen, made from the patient's virus. In addition, it was of some interest to use properly diluted psittacosis antigen in skin tests on the patient, since serologic studies had brought out the usual cross reaction noted for this group of viruses.¹⁹ The last two antigens were diluted in the following manner: yolk sacs were calculated to weigh 1.5 gm. each, and the dilutions were made up to 1:25, 1:50 and 1:75 — that is, 1 part of infected yolk sac was suspended in 25 parts of buffered-saline solution and so forth. Similar dilutions of normal yolk-sac suspensions were used as controls. For testing, the usual 0.1-cc. intradermal injection of each dilution was made, and daily measurements of the lesions were made for seven days. As can be seen in Table 3, Lygranum S. T., the L. A. antigen and the Army Medical School antigen gave positive results, whereas the psittacosis antigen was negative.

Discussion

The diagnosis of these cases as lymphogranuloma venereum was based on the clinical history and physical findings, the positive complement-fixation tests, the positive Frei tests and, in Case 1, the isolation of the virus from the patient. The etiologic relation of the virus to the meningoencephalitic changes is, of course, based on circumstantial evidence — that is, the involvement of the central nervous system along with the virus infection, the knowledge that this virus can produce meningoencephalitic signs in experimental animals, the fact that the virus has been isolated from '... (L.A.)'

TABLE 4. Cross-Immunity Tests in Mice.

2	A. M. S.	L. A.	0,0,0,0,0,0,0	3,4,8,5,5

*The numeral indicates the day of death of the mouse following the test inoculation. S indicates that the animal showed definite signs of illness but survived at least ten days, 0 means that the animal remained well throughout.

†This mouse probably died of intercurrent infection

heterologous strain. Control mice were inoculated in each case. The animals were observed daily. The findings, which are presented in Table 4, strongly indicate similarity of identity of the L. A. and the known lymphogranuloma venereum strains of virus.

Complement-fixation studies were utilized not only to determine the presence of specific complement-fixing antibodies in the patient's serum, but also as an ancillary aid in identifying the virus isolated from him. The findings are summarized in Table 2, from which it can be seen that these tests were carried out with three different antigens, namely, Lygranum C. F., psittacosis antigen and an

Sabin and Aring reported inability to immunize mice by intraperitoneal inoculation with strains of virus isolated from their patient, as well as with known lymphogranuloma venereum virus

other patients with the disease^{3, 6} and the negative serologic results in tests against other encephalitis-producing virus agents. Final proof that lymphogranuloma venereum can cause meningoencephalitis in man must await isolation of the virus from the brain substance in a fatal case and the demonstration of histopathologic changes in the brain tissue consistent with those produced by the virus in experimental animals.

On the basis of the spinal-fluid dynamics (Table 1), Case 1 presented a complete spinal block throughout the eight months he was observed. It is believed that the meningeal involvement early in the course of his illness resulted in subarachnoid block. This syndrome is known to occur in patients with acute purulent meningitis, tuberculous meningitis, yeast meningitis and syphilitic meningitis.²⁰ Since these causes seem to have been excluded by means of cultural and serologic studies, it appears probable that the adhesive arachnoiditis encountered in this case was a residuum of the lymphogranuloma venereum infection.

In addition, certain other features of the spinal-fluid findings are of interest. The total protein content reached 3570 mg. per 100 cc., gradually diminishing in amount as the patient improved. None of the specimens clotted after standing. The question arises whether the great increase in protein content was the result of the subarachnoid block per se, of the meningeal involvement or of both these factors. Such high levels of protein are encountered extremely rarely, even in the presence of cord tumor.²⁰ In this patient, the amount of protein gradually declined from 3570 to 114 mg. per 100 cc. It does not appear that this decline was due to the progressive removal of protein by repeated lumbar punctures, since the intervals between them were about the same both when the protein content was extremely high and when it was relatively low. This suggests that the accumulation of protein occurred at a progressively diminishing rate and was therefore not caused by the block alone. Furthermore, Sabin and Aring⁶ found that the amount of protein reached 1400 mg. per 100 cc. in the spinal fluid of a patient who presented no evidence of obstruction. Thus, although in the present case the subarachnoid block undoubtedly was a factor, the more important cause of the great increase of spinal-fluid protein was probably the meningitis, which in turn was probably due to lymphogranuloma venereum.

It is of additional interest to note the character of the colloidal-gold curves, which were uniformly of the paretic or first-zone type. On two occasions, twenty-tube tests were performed in order to obtain end-point readings, and the curves were 5555555555, 5555432000 and 5555555555,4311000000, respectively. Merritt and Fremont-Smith²⁰ have concluded on the basis of their wide experience that this test has no specific diagnostic import and that precipitation of the colloidal-gold solution is indicative only

of an abnormality in the protein content of the fluid. That this was the case in this patient appears to be borne out by the data presented in Table 1.

Infection with the lymphogranuloma venereum virus is known to persist for a long time,² so that it is not surprising that the L. A. virus was isolated from a lymph node that had been slightly enlarged for five months. It seems significant, however, that the histopathologic changes observed in this node were nonspecific and not at all suggestive of involvement with this virus.

Isolation and identification of the virus is a too elaborate and slow procedure to be used for routine diagnostic purposes. The complement-fixation test thus becomes an especially valuable adjunct in the early diagnosis of infection with the lymphogranuloma-psittacosis group. Unfortunately, with the antigens now in use it is not possible to differentiate these closely related viruses.¹⁹ This similarity was observed in the complement-fixation results with the serums from these two cases (Table 2) and, as mentioned before, other evidence is necessary in order to establish the diagnosis.

The complement-fixation test was also used as a means of identifying the L. A. virus. An antigen was made from yolk sacs infected with the L. A. virus and was used in tests with serum from both patients and from a known case of psittacosis. Positive reactions were obtained with all the serums.

Negative results with Frei tests are not infrequently observed in lymphogranuloma venereum infections. Only one of eight tests done in the case reported by Sabin and Aring⁶ was positive. In Case 1, positive tests were not obtained until the eighth month of illness, and included a positive reaction to an antigen prepared from the virus isolated from the patient. Because of the cross reactions noted in the complement-fixation studies, he was also tested against a psittacosis antigen, with a negative result. So far as could be ascertained, there have been recorded no extensive series of tests on known lymphogranuloma patients with psittacosis antigen, so that the significance of this single observation cannot be evaluated.

SUMMARY

Two cases of meningoencephalitis in patients with lymphogranuloma venereum are presented.

A virus was isolated from an inguinal lymph node of one patient five months after the onset of illness, in spite of the fact that the histopathologic changes in the lymph node were nonspecific.

The virus was identified as lymphogranuloma venereum by its effect in mice, guinea pigs and developing chick embryos, by cross-immunity tests in mice and by complement-fixation studies.

Mice were immunized to this virus and to another strain of lymphogranuloma venereum by intraperitoneal injection.

Subarachnoid block, an extremely high total protein and first-zone colloidal-gold curves were observed in one patient. These findings are discussed.

Positive Frei tests were obtained on one patient with an antigen made from the virus isolated from him, as well as with other yolk-sac antigens. An intradermal test on the same patient with psittacosis antigen was negative.

I am indebted to Captain J. E. Smadel, M.C., A.U.S., for his assistance and guidance through much of the experimental work; to Captain E. Roseman, M.C., A.U.S., for supplying the clinical data on Case 1; to Major C. R. Rein, M.C., A.U.S., for special studies on the spinal fluid of Case 1, to Captain H. L. Hamilton, Sn.C., A.U.S., for carrying out the chick-embryo aspects of the work; and to Lieutenant J. Wertman, Sn.C., A.U.S., for his supervision of the complement-fixation studies.

CARCINOMA OF THE THYROID GLAND WITH A SOLITARY METASTASIS TO THE SKULL

Report of a Case

HOLLIS L. ALBRIGHT, M.D.*

BOSTON

THE characteristically slow growth of the solitary metastasis of carcinoma of the thyroid gland to bones, notably to the skull, has been repeatedly observed. In 1871, Mueller¹ noted the tendency of metastatic lesions of the thyroid gland to appear microscopically benign. Cohnheim² was led to regard the primary thyroid lesion as a so-called "benign metastasizing adenoma." He used this paradoxical term in an attempt to explain the long-standing presence of the primary tumor in the thyroid gland and of metastasis to the skull without the usual progressive spread and early death so often seen in other forms of malignancy. More recent studies by Simpson,³ Dinsmore and Hieken⁴ and Graham,⁵ and the opinions cited by Turner and German⁷ after their recent careful review of the literature have led to the conclusion that there is no such entity as a benign metastasizing adenoma. Turner and German believe that this type of thyroid tumor is actually a malignant adenoma. In their experience, painstaking microscopic examination of the entire tumor has, in most cases, shown tumor-cell invasion of the blood vessels, stroma or capsule of the adenoma.

These slowly growing metastatic lesions in the bones, prominent in the skull, vertebrae and pelvis,

may be solitary or multiple. In some cases the lesion may exhibit arterial pulsation, but this is not always present. Because of the slow growth and the relatively isolated nature of the skeletal metastatic lesion, attempts have been made from time to time to remove both the original tumor and the metastatic lesion surgically. In 1941, Turner and German⁷ reported 2 cases in which removal of multiple thyrogenic skull metastases was attempted. The first patient had extensive metastases to the skull but survived the operative removal for three years, ultimately succumbing to progressive metastatic spread. One year after operation, a tender, nodular liver developed, followed by the appearance of further metastases in the skull and in the cervical lymph nodes. The second patient had metastases to the skull, pelvis, coecum and kidneys at the time of operation and died of uncontrollable hemorrhage following attempted removal of the extensive skull lesions. The hemorrhage occurred during elevation of the bone flap.

Friedman⁸ has recently reported 2 cases operated on subsequent to January, 1942, with immediate success in removal of both the primary thyroid tumor and the skull lesion.

In the case reported herein, there was a visible solitary metastasis to the right temporofrontal region of the skull and a previously unnoticed large

removal, first, of the primary malignant adenoma of the thyroid and then of the skull lesion, which had been proved by biopsy to be thyrogenic.

CASE REPORT

R. S. C., a 52-year-old, Italian housewife, was first seen in the Tumor Clinic of the Massachusetts Memorial Hospitals on December 6, 1940, at which time she complained of a painless lump on the right upper forehead. Four months previously, the lump had appeared immediately after she struck this part of her head against the corner of a medicine cabinet. It had not changed in size and was not painful or tender. She had, however, noted occasional mild right-sided headaches since the injury, and recently a slight discomfort in the region of the lump itself. She stated that her general health was excellent, and that she had no other complaints.

Examination disclosed a mass in the right lobe of the thyroid gland, which the patient had not known to be present. Consequently, she was admitted to the Surgical Service on December 12, 1940, for study. In the right frontal area there was a moderately firm, nontender mass measuring 2.5 by 1.0 cm. This was thought to lie in a bony defect with some elevation of the outer table of the skull. A nonexpansile arterial pulsation was felt, and there was some increase in tension when the patient coughed. In the right lobe of the thyroid

FIGURE 2. Photomicrograph of a Section of the Thyroid Tumor.

normalities. A blood Hinton test was negative. Lumbar puncture showed an initial pressure equivalent to 180 mm of water. The spinal-fluid cell count was 3 lymphocytes per millimeter, with the sugar 79 mg. per 100 cc. and the globulin not increased. The gold-sol curve and Wassermann reaction were negative, and the total protein was 16 mg. per 100 cc. The basal metabolic rate was +11 per cent.

X-ray examination of the skull showed a 3-cm. defect in the right frontal area, involving both tables, with slight surrounding condensation of the bone (Fig. 1). X-ray films of the trachea showed some displacement to the left, with lateral and anterior compression. A calcified mass could be

FIGURE 3. Photomicrograph of a Section of the Skull Tumor.

seen in the region of the right lobe of the thyroid gland. The chest showed increased fibrosis and no metastases. X-ray films of all the long bones revealed no other lesion. Intravenous pyelograms were negative.

The patient was seen by the neurological consultant, Dr. Theodore J. von Storch, whose impression was that there was no intracranial involvement from the mass other than a questionable slight pressure on the right frontal lobe.

On December 28, Dr Howard M. Clute performed a right total thyroidectomy and a biopsy of the tumor in the right frontal area. Pathological examination of the tissue was reported by Dr Charles T. Branch as follows:

The specimen consists of a lobe of thyroid tissue measuring 8.0 by 4.5 by 3.0 cm and weighing 50 gm, some what pear shaped, the smaller end representing the upper pole. The lower three quarters of the gland is represented by a firm, partially calcified, encapsulated irregularly

FIGURE 4 Appearance of the Patient Two Months after Removal of the Skull Metastasis

Note the diamond-shaped skull defect, as well as the thyroid scar, three months after removal of the primary tumor

rounded nodule approximately 4 cm in diameter. On section fully two thirds of the central part of this mass is found to be stony hard and calcified. Its periphery, however, is composed of soft, pliable, smooth glistening reddish brown meaty appearing tissue in which no normal acinar tissue can be discovered.

Microscopic section through the nodule shows it to consist of closely set cords of small, hyperchromatic epithelial cells having all the appearance of embryonal thyroid tissue (Fig 2). In certain areas these cords open up to form well defined lumens of fetal character containing a small amount of poorly staining colloid substance. There is definite vascular invasion. In spite of their embryonal nature, careful search shows relatively little anaplasia of the epithelial cells, and mitoses are extremely rare.

Section through the biopsy specimen from the skull (Fig 3) shows a histologic picture practically identical with that above described. Here the cells are slightly more anaplastic, and show a few more mitoses and less evidence of regular alveolar arrangement. Here, also, there is distinct evidence of vascular invasion.

Diagnosis. Thyroid gland small cell carcinoma arising from embryonal adenoma and showing vascular invasion. Skull lesion metastatic carcinoma from thyroid gland, showing local vascular invasion.

The postoperative course was satisfactory, although marked by a rise in temperature to 103.2° on the 2nd day, followed by a gradual fall to normal. Both the thyroidectomy and skull biopsy wounds healed well. Much discussion among the surgical staff and the neurosurgical consultant, Dr Donald Munro, led to the belief that in view of the slowly progressive nature of the apparently solitary metastatic tumor, an attempt at radical cure by excision of the skull lesion with subsequent radiation therapy was indicated.

The patient was therefore transferred to the Neurosurgical Service of the Boston City Hospital on January 9, 1941 for further treatment. On January 27 craniotomy was performed by Dr Munro, and the metastatic tumor was removed. It was found that although the dura was depressed by the growth, only its outer layer was involved and there was no perforation. Convalescence was satisfactory, and the patient was discharged home on the 10th postoperative day. On this day x-ray therapy was begun, consisting of a series of ten doses of 200 r each, directed at the right temporo-frontal area and given over the course of 1 month.

When seen 2 months after the second operation, the patient had no significant complaints. There was a diamond shaped skull defect measuring 3 by 3 cm (Fig 4), with definite pulsation in the area, but with no palpable masses. The body weight had remained static.

FIGURE 5 Appearance of the Patient Two Years after Operation

When last seen 2 years and 6 months after the second operation the patient was having no difficulty of any sort. She felt entirely well and had gained 6 pounds. There were no palpable masses or evidences of recurrence at either operative site. The defect in the skull had a firm fibrous base. The giving sound protection to the underlying brain tissue. The patient's appearance was entirely normal with normal coverage and distribution of hair (Fig 5). A check up x-ray examination of the skull in December, 1942 showed a smooth outline of the skull defect with no evidence of recurrence or metastatic spread (Fig 6).

DISCUSSION

The subject of treatment of this disease is a controversial one. In this case, two years of normal health and apparent freedom from metastatic malignant disease seem to have validated the judgment of the physicians involved. Some writers have expressed reluctance to subject a patient to such

FIGURE 6. X-ray Film of the Skull Two Years after Operation.

Note the smooth bony outline of the defect.

radical palliative surgery. Hamann,⁹ in reporting a nonoperable case in 1916, expressed the then prevalent opinion as follows:

As has been pointed out by Bland Sutton and others, metastatic deposits in the skull, manifesting themselves as pulsating, vascular tumors, occur sometimes, secondary to thyroid carcinoma; such metastatic growths are, of course, quite inoperable, as the writer can confirm from an experience in one case in which attempt to remove the growth had to be desisted from, owing to the large size of the blood-vessels.

Cruickshank,¹⁰ however, in 1938 reported the successful removal of a tumor from the right frontal area of a fifty-five-year-old Hindu woman. This tumor was thought to be a meningioma, but pathological examination revealed typical thyroid tissue. Control of hemorrhage had not been troublesome. Four months later a nodule the size of a hazelnut was discovered in the right lobe of the thyroid gland, but the patient refused further operation,—that is, thyroidectomy,—and follow-up studies were not reported.

Barthels¹¹ has stated that the carcinoma of the thyroid gland that produces bone metastases is of relatively low virulence, and that therefore to remove a single metastatic lesion cannot be described as meddlesome surgery.

Neither the thyroidectomy nor the skull operation proved to be of such formidable nature as to cause severe discomfort or to occasion a prolonged hospital stay. The patient left the hospital seven days after the thyroidectomy and ten days after partial craniectomy, without further disability. Her further course will be studied with interest. Certainly effective palliation has been gained in a situation that had appeared advanced and inoperable.

SUMMARY

The case of a patient who had a carcinoma of the thyroid gland and a single skull metastasis and who showed no evidence of recurrence two and a half years after the surgical removal of both lesions is presented, and pertinent references in the literature are discussed.

MEDICAL PROGRESS

GYNECOLOGY: CARCINOMA OF THE CERVIX

JOE V MEIGS, MD*

BOSTON

CARCINOMA of the cervix is the commonest malignant tumor occurring in the genital tract in women, ranking closely in frequency with cancer of the breast. Its presence may be detected extremely early, for among its symptoms are bleeding and discharge. The tumor can be seen and felt, and is accessible to biopsy. The new vaginal smear technique,¹ which will be described later, also enables its presence to be detected.

The results of treatment, either radiologic or surgical, are excellent in early cases, yet this disease is found in its early stage in not over 20 per cent of patients seen. The present review of the progress made in all phases of cervical cancer shows that although the results should be markedly improved, they are not. Lack of careful periodic examination of the cervix, appreciation of the significance of abnormal discharges and bleeding and of frequent biopsy of the cervix accounts for many advanced cases. It is also true that patients who have had no symptoms are seen with advanced disease. There is ample evidence, however, that more careful attention to early symptoms and more careful investigation by physicians would result in surgical treatment in the early stages. The results of treatment seem to have reached a level beyond which it is difficult to go. There is no doubt that certain specially treated and studied groups of cases do better than those routinely treated, but on the whole most of the results of the largest cancer clinics show about the same percentages of arrested or cured cases. In other words, it is obvious that more cures will come from earlier diagnosed cases and also from more individualistic treatment.

The theory that all cases should receive combined radium and x-ray treatment, in a routine manner, is not sound. The radiologist should see the tumor and map it out so that he can better aim his x-ray tube at each treatment. The radium available should be of all types and strength. The choice of applicators and needles should be made at the time the treatment is given and not planned before the patient is under an anesthetic, or before x-ray treatment is completed if the latter is given before the radium treatment. Most clinics have radium in certain strengths and in certain types of needles, and this limits the possibility of variation in its use.

The tendency is to have rules for treatment of the various classes of the disease and to give the treatment always in the same manner. Instead, it should be varied to meet the type and extent of the disease in each case. Every clinic has its set method of treatment, and in each the operators are convinced of the perfection of their method, yet, as already stated, in the end the largest clinics have the same percentage of cures. It is therefore obvious that new methods of attack on the problem must be tried and that treatment should be directed to the cure of the patient whether or not it consists in the giving of x-ray or radium or in surgery. Tausig's² work, to be discussed later, is an example of individualization of cases and the results of his method of treatment are, in his hands, strikingly better than those in most clinics. Miller,³ of the University of Michigan Hospital, expresses the following viewpoint, which is probably the correct one:

The limitations of existing methods of treatment are well recognized. No one expects the impossible but there is good reason to believe that therapy is disappointing. We appear to have reached that comfortable state wherein we hesitate to disturb the efficiency of a therapeutic system which has taken a long time to establish. Perhaps

well as the apparent effective has lulled us into a state of exploit existing methods of treatment to their fullest capacity. In radical abdominal hysterectomy, as first performed by W. A. Freund in 1878 and later popularized by Wertheim, was recognized a potent weapon for combating cervix cancer. But because of its high primary operative mortality rate and its restricted field of usefulness the operation was permitted to pass into the discard. Radium and x-ray have also proved their worth. Yet after almost a quarter century devoted to the refinement of technique and stabilization of procedure I find there is little to boast about. Perhaps we have reached the end of an era. Perhaps if we could see into the future we might visualize as the cancer therapist not the radiologist nor the gynecologist nor the surgeon but possibly the chemist. It is not beyond the realm of possibility that radium may some day become a drug on the market and deep x-ray therapy equipment an excellent source of copper wire and other spare parts. The limited capacity of existing remedial measures is definitely responsible for some of our restricted success but any attempt to blame results on this basis alone might more properly be attributed to an indolence on our part—a failure to exploit to their fullest efficiency radium x-ray and surgery or a combination thereof—a serious failure to give these methods of treatment a fair chance. In both irradiation therapy and surgery we have potent weapons. Perhaps neither has been developed to its fullest efficiency. Given an opportunity, these methods may still accomplish what we have a right to expect in the way of vastly improved survival rates.

It is certain that advances will be made in the treatment of this condition. Papaniolaou and

*Clinical professor of gynecology, Harvard Medical School, chief gynecology service (V. Vincent Memorial Hospital), Massachusetts General Hospital.

Traut's⁴ work on the vaginal smear, Schiller's^{5, 6} observations on the staining of the cervix, Hinselmann's⁷ use of the colposcope, Taussig's² demonstration of the ease and efficacy of lymph-node dissection and our own demonstration⁸ of the safety of the radical operation for cervical cancer, when aided by the methods of modern surgery, furnish evidence that more possibilities are open now than ever before.

ETIOLOGY

There is no doubt that most cancers of the cervix occur in women who have borne children, but nulliparas make up 5 to 10 per cent of the patients seen in cancer clinics. It is possible that the important factor is not the lacerations themselves but the resultant infections and irritations. Thus, in nulliparas who develop this disease it is conceivable that an endocervicitis or some such lesion as a so-called "congenital erosion" of the cervix has been present. A young girl with menorrhagia recently seen in our clinic had such an erosion. Ten years later the whole area affected was replaced by carcinoma.

Wharton⁹ quotes Pearl as stating: Of 100 American women about 70 are parous and 30 nonparous. In other words, their ratio is as $2\frac{1}{4}$ to 1, but the incidence of cervical cancer, on this basis, is as 19 to 1. In other words, with due correction cervical carcinoma is approximately eight times more frequent in parous than in nonparous women. These data indicate that pregnancy or labor does something which predisposes toward cervical cancer.

Severe irritations of the cervix, such as those occurring in patients with procidentia, rarely end in cancer.

Sorba¹⁰ believes that syphilis plays a part in the development of cervical cancer, for 262 patients, or 14 to 15 per cent, of those seen in his clinic had the disease, whereas the percentage of syphilis in other patients was only 1.6 per cent. He thinks that syphilis gives impetus to the cancer. Reports from American clinics do not give such high percentages of syphilis in patients with cancer of the cervix.

Heredity probably plays a role in the etiology of tumors, but a family history of carcinoma is not often present. Imamura¹¹ found such a history in 9.4 per cent of patients with tumors of the uterus. Wassink,¹² of Holland, in discussing carcinoma of the breast, stated that in many cases there was a family history of carcinoma of the uterus. In our clinics at the present time there are two pairs of sisters with cervical cancer. There is probably a certain amount of truth in the theory of heredity, but in the large majority of cases no family history of cancer is found.

It is interesting to note the infrequency of cervical cancer in Jewish women. Smith¹³ found it to be about 5 per cent in the clinic of the Memorial Hospital (New York City), and Healy and Twombly,¹⁴ reporting from the same clinic, stated that only 5 per cent of 920 women patients were Jewesses. This absence of cervical cancer in Jewish women can

be explained by breeding out of the disease, since it is apparent that Jews have bred in diabetes and hypertension, or by the Mosaic law in relation to sex, for observance of this law results in the fact that intercourse does not occur during or shortly after the period, when the cervix has just gone through the changes incident to menstruation.

Theories of a hormonal origin have been proposed, and both the pituitary gland and the ovary are considered as possible etiologic factors. Hofbauer¹⁵ believes that the influence of the pituitary gland on the cervix is great, yet this influence must not be direct but through the ovary, which produces estrin and progesterin under pituitary influence. Estrin is a growth-producer and is responsible for changes occurring in the cervix. It is well known that Hisaw¹⁶ has been able to produce cancerlike lesions in the cervix with estrin, but the lesions are not real cancers, and are cured by progesterin. It is also known that cervical polyps may take on a cellular activity that is similar to cervical cancer during pregnancy. The polyps have a cancerlike appearance when examined microscopically but are not true cancers. The changes are due to some hormonal influence, probably that of estrin. Gardner, Allen, Smith and Strong¹⁷ have been able to produce cancer in the cervixes of mice by the use of estrin. These tumors metastasize and can be grafted and grown without more estrin. Other experimenters have produced cancer with estrin in other organs in the animals, but there is no proved case of production of the disease in a human being in this manner. In patients with cancer of the genital tract, however, estrin therapy should be avoided until it has been proved to be safe.

There is no known etiologic factor in cervical cancer, but childbearing, lacerations, infections, syphilis, hormones and heredity all play a part. A tendency to cancer must be present, and some other factor must be the spark that starts the fire.

SYMPTOMATOLOGY

No new symptoms have been described to suggest the presence of cancer of the cervix, but meticulous attention must be paid to abnormal bleeding or discharge, whether spontaneous or following douching or intercourse. When continuous bleeding, discharge or pain occurs, the cancer has probably grown beyond the early stage. Miller¹⁸ states that the most significant early symptom is abnormal bleeding.

DIAGNOSIS

There have been added to current diagnostic methods three extremely valuable aids.

Schiller's⁶ test is valuable if its indications are interpreted correctly. Schiller used Lahm's discovery that in cancer of the cervix the epithelium lacks glycogen, which is present in normal cervical epithelium. He therefore thought of iodine, which

stains glycogen, as a test for its absence. He advocates a solution made up of 1 part iodine, 2 parts potassium iodide and 300 parts distilled water. In our clinics this solution has not been found satisfactory, since it stains too lightly; the amount of iodine has therefore been increased to 2 parts and that of potassium iodide to 4 parts. This solution is highly satisfactory. Iodine is poured into the vagina, left for two or three minutes and gently reabsorbed with cotton, and the cervix is then viewed.

The most valuable aid that can be obtained from Schiller's solution is indication of the area from which a biopsy specimen should be taken. Any area that stains a homogeneous dark brown can be considered normal, and any area without a stain should be biopsied. Light-brown areas are usually those of diseased or infected epithelium. Superficial cancer does not stain, nor do hyperkeratotic areas due to prolapse, similar areas due to syphilis, or desquamation of the upper layers of the epithelium. Schiller advocates scraping off the abnormal area with the sharp edge of a spoon and fixing and staining, but it is safer to excise the area with tissue on all sides of it. A positive Schiller reaction does not mean that cancer is present, but it does indicate abnormal changes in the cervix, and these should be viewed with the microscope.

The colposcope of Hinselmann is also of great value, not so much for the actual discovery of early cancer as for showing the operator what the cervical epithelium looks like. Once the examiner learns the appearance of the normal cervix, he begins to see abnormal areas and recognizes some of them as due to infection, cysts, exposed ducts and so forth. He also recognizes areas of ulcerated or hypertrophied epithelium divided by fine lines into squares and takes biopsy specimens from them. The use of Schiller's iodine solution in conjunction with the colposcope further demonstrates abnormal cervical epithelium. It has never been my good fortune with either of these tests to find a cancer of the cervix that had not been suspected, yet the amount of information obtained from the study of the cervix by these methods has been enormous and no doubt contributes to one's ability to recognize early, suspicious areas of cervical epithelium. Certainly the constant use of these two methods is of extreme value to the examining physician.

The diagnosis of cancer of the cervix by means of the stained vaginal smear was first introduced by Papanicolaou and Traut.¹ Their work was substantiated by the investigation of Meigs, Graham, Fremont-Smith, Kapnick and Rawson.¹⁹ There is no doubt of the value of this method, and the percentage of correct diagnosis is extremely high. A positive smear usually results in a correct diagnosis, but a negative one means little; the latter is comparable to the negative Wassermann reaction, which does not mean that syphilis is not present.

The apparently false-positive smear has yet to be proved. To do this would mean taking out the whole uterus and cutting serial sections along its entire length. The positive smear, in the absence of obvious cancer, may be a means of detecting extremely early growths. This part of the research has not been concluded. It is also possible to differentiate cancer of the endometrium from cancer of the cervix by the smear. A description of the method of taking the smears, the fixing and staining and the interpretation of results is given by the authors mentioned above. This method of diagnosis constitutes an epochal advance, and with Schiller's iodine and the use of the colposcope should aid early diagnosis. Possibly every woman over the age of thirty should have routine vaginal smears done once or twice a year, and be checked by the Schiller test and the colposcope at least once a year. A positive smear means that an investigation should be carried out under anesthesia. The uterus should be dilated and curetted and specimens of the cervix removed for microscopic section.

Biopsy. Study of the cervix by means of biopsy is the most important of the diagnostic aids. The specimen should be taken with supposedly healthy tissue on all sides of it. This is not always possible in the office, but it can always be done under an anesthetic. The disadvantage of the biopsy is that it can be negative and yet cancer can be present in the cervix. To be sure that it is not present, nearly all the cervical tissue would have to be removed. By means of the iodine test and the colposcope the most suspicious area can be demonstrated and biopsied.

CLASSIFICATION

The subject of classification is not necessarily included in a discussion of progress, but unless a single classification is universally agreed on, results and treatment cannot be compared. Comparison of the results in various clinics is at best inaccurate, but with different methods of classification adopted it is rendered even more so.

It is essential that tumors be classified, for certain clinics have a greater preponderance of early cases than do others. Cancer hospitals where patients can remain for treatment usually have larger numbers of advanced cases than do general hospitals. Since the League of Nations classification²⁰ is being universally accepted as the proper one, it is being favored more and more by American clinics. This classification is more complicated than the earlier one of the American College of Surgeons or the Schmitz²¹ method, and is not a great improvement.

The microscopic grading of the actual tumors is based on the individual ideas of the pathologist, and each one teaches his associates and students accordingly. It is doubtful whether there ever will be a standard method of grading tumors, but the

Martzfloff^{22, 23} method is to be recommended. His cases are grouped as those with spinal cells or low-grade malignancy, those with transitional cells or medium-grade malignancy, those with fat spindle cells or high-grade malignancy and those with adenocarcinoma. If Martzfloff's method could be used everywhere, great knowledge would accrue, but that it will ever become universal is unlikely.

Chambers²⁴ reports that in his attempt to grade 728 cases, 228 could not be classified because of insufficient tissue. Ten per cent were adenocarcinoma. Of the entire series, 15 per cent were Grade I, 9 per cent Grade II, 54 per cent Grade III and 22 per cent Grade IV—with extremely rapid growth. Chambers finds some indication that the more undifferentiated growths are frequent in youth and that there is no relation between the duration of symptoms and the extent of the disease, and states that most growths involving the cervix alone were cured without respect to their grade. Wetterdal²⁵ finds the percentage of cures of different grades to be so similar that the microscopic appearance of the cancer is of no apparent prognostic value.

Cancer of the cervix in gross may be of the cauliflower type and evverting, or ulcerating and inverting. It may involve the entire endocervix without breaking the mucous membrane of the cervix. It may appear early and yet involve the pericervical tissues and even extend laterally to the pelvic walls. It may be early and appear to be localized and yet have metastasized widely. It may produce enormous growth into the vagina and yet have a favorable prognosis, no extension having occurred into the vagina or pelvis.

Microscopically, cancer of the cervix is usually squamous-celled or epidermoid. About 6 per cent of the tumors are adenocarcinomas according to nearly all authors, and the results either with combined radium and x-ray or with surgery are the same as those in the epidermoid types. All tumors of the endocervix are by no means adenocarcinomas; most of them are epidermoid or squamous, the tumor probably arising from areas of embryologic squamous epithelium resting in the endocervix or from areas of metaplasia. Simpson, Thibaudeau and Burke²⁶ say that the ratio of adenocarcinoma to squamous-cell carcinoma is 1:26. Incidentally, 20 patients (32 per cent) of their 63 patients with adenocarcinoma were nulliparous.

TREATMENT

In a paper such as this it is not pertinent to go into the details of treatment used by each clinic. The references will guide anyone interested to the proper papers related to the subject.

Some clinics prefer to use radium alone in the treatment of this disease. The radium is applied in the canal of the cervix, against the cervix, against the sides of the cervix in the vaginal vaults, in square

boxes or colpostats, interstitially by means of glass, gold or platinum seeds, or interstitially by means of platinum needles ranging in strength from 1 to 50 mg. The radium in some clinics is in the form of radon; in others, the platinum-encased salt is used. Certain operators prefer a small amount for a large number of hours; others prefer a large amount for a small number of hours. Some space the treatments four days, seven days or two weeks or more apart.

The use of x-ray treatment is much commoner than formerly, and some clinics employ it as an adjunct to radium, giving it when it is thought that the broad-ligament extensions are not being treated satisfactorily, whereas others use it as an integral part of the treatment. In the latter group it is given either before or after radium treatment. Some surgeons give radium first, then x-rays and then radium again. X-ray treatment is adopted either in an attempt to destroy cancer in the pericervical tissues or broad ligaments and lymph nodes, or to cause cicatrization of the lymphatics of the broad ligaments and destroy lymph-node extensions.

There are many combinations of treatment, and without doubt in every clinic at some time every possible combination has been used. It is interesting that out of the wealth of experience no one method of treatment has been so satisfactory that it has been universally adopted. Apparently, any well-applied treatment that gives radiation in lethal doses to the entire tumor and its surrounding tissue is all that is necessary, and this may be accomplished in a great many ways. It is almost universally agreed that x-ray treatment cannot destroy cervical cancer in lymph nodes. Thus, surgical removal is necessary, but in most clinics it is not used. Bonney²⁷ writes:

I have on many occasions, at the close of the operation, discovered an infiltrated gland or mass of infiltrated cellular tissue so adherent to the great vessels as to be irremovable. All of the patients were treated by x-ray, but in spite of a definite target to aim at not one was saved.

The use of x-ray treatment to reduce the size of the cervical growth and cicatrize the broad ligaments, and perhaps to destroy cancer in the lymphatics, is proper. There are those who use x-rays to cross-fire the cervix, hoping to aid the radium in its action, and there are others who direct them straight through the pelvis to injure or destroy the growth lateral to the cervix. All methods are helpful, but no single correct one has been evolved. One of the most important functions of the roentgenologist is to direct the rays at the tumor; yet in many institutions the aiming is left to x-ray technicians. This is a weak point of roentgenologic treatment. From observation of patients treated by x-ray in the early days, it is obvious that the treatment was directed much too high, as evidenced by telangiectases.

The addition to the x-ray armament of the 500,000-volt and 1,000,000-volt machines may or may not be a distinct advance. A sufficient number

of cases over a sufficient number of years to allow any positive statement have not been reported. It is the opinion of the surgeons attending the clinic at the Massachusetts General Hospital that we have not yet learned how to use the 1,000,000-volt machine to the best advantage, and that it will may be that through trial and error we shall hit on the proper dosage. It is our opinion that at times this machine performs wonders, but so does the 200,000-volt machine. It is too early to know what voltage is best.

Merritt²⁸ advocates the use of the vaginal cone in administering x-ray treatment to the cervix. This is done through Ferguson speculums, and a total dosage as high as 6000r may be given. This method may have value, and further reports of its results will be eagerly awaited. So far, Merritt has treated 112 patients. He believes that his results are better than those attained with many additional portals and with radium alone.

To sum up, x-ray and radium alone or in combination usually destroy cancer involving the cervix, the cervix and vagina, and the cervix, vagina and pericervical tissue, if it is not in the lymph nodes. Yet there are certain radioresistant tumors that they cannot destroy. Furthermore, a satisfactory destructive dose cannot be given in the advanced stages of the disease without also destroying the bladder and rectum and other important organs.

In 1933, Leveuf, Herrenschmidt and Godard²⁹ advocated the removal of nodes in pelvic cancer, believing that although cancer of the cervix can be cured by x-ray treatment, lymph-node extensions cannot. In 1934, Taussig³⁰ first reported the results of dissections of the lymph nodes in a group of patients who had node extension as felt by pelvic examination (Stage II, League of Nations classification). His dissection was done before, during or after radiation, depending on when the patient was admitted to the hospital. Taussig believes that combined radium and x-ray treatment will cure the local disease but that surgery must be employed to cure lymph-node extensions.

I had the privilege of seeing the late Dr. Taussig operate and watched his meticulous dissection of the lymph nodes and lymph chains in the region of the common iliac artery, that of the external iliac artery and vein, that of the internal iliac or hypogastric artery and that of the obturator foramen and its nerve. Some of the nodes were not over 1 mm. in diameter, yet cancer was found in them, whereas in some of the larger ones no cancer was found. Taussig at times found it necessary to resect the external iliac vein during his operation. The only area that to an observer was not satisfactorily cared for was that near the ureter, and there it would have been necessary to tie off both uterine arteries to do a proper dissection. Taussig believed that combined radium and x-ray treatment was satisfactory for this area. As reported in his last paper,³¹

he operated on 175 patients with a mortality of only 2 per cent. Of 70 patients in Class II of the League of Nations classification, 37 per cent were living and well after five years. In a parallel group of 118 patients treated by radiation alone, the five-year salvage was only 23 per cent. In other words, Taussig demonstrated a 68 per cent greater salvage if lymph-node dissection was added to radiation. In 27 per cent of his cases cancer was present in the lymph nodes; 21 per cent of these patients were well after five years. If their treatment had been left to radiation alone, probably none would have survived.

Because combined radium and x-ray treatment has failed to be more successful, because of the damage that can be done with radium, because of Bonney's and Taussig's success in dealing with the lymph-node problem, and even more because of Lynch's³² work, which showed viable cancer in the cervix after satisfactory radiation, the question whether the radical or Wertheim-Clark operation should be revived is pertinent. Bonney in England and Lynch and Morton³³ in California advocate radical surgery, and I have now joined them. Bonney has operated on 500 patients with a mortality of over 9 per cent. He has treated advanced cases and has had to resect veins, arteries, the bladder and the bowel, and has attacked any cases that he thought he could possibly handle. It is difficult to compare his results with those following any form of radiation treatment, but they are excellent. It is obvious that before the operation can be universally adopted the mortality must be lowered. Bonney has kept 40 per cent of his patients well for five years, but he could not operate on all cases. Of his 500 patients, 300 had normal lymph nodes and 200 had cancerous nodes. His ability to cure lymph-node extension is the same as Taussig's, about 22 per cent of his patients surviving for five years.

It occurred to me after reading the reports of Bonney and Lynch and seeing Taussig's work that in selected good-risk patients the radical surgical operation could be done with less mortality and perhaps with as good results as those of radiation, and with a chance to cure certain patients with lymph-node extensions. The operation has been carried out in 57 cases; the mortality was zero, but the incidence of injury to the ureter was unexpectedly high — 10 per cent. The lymph nodes were involved in 16 per cent of the cases. The results indicate, however, that a judicious selection of patients for x-ray, radium or surgical treatment is going on that may lead to new heights of curability. The acme of radiation therapy has not been reached, but it can certainly do no harm to operate on patients with radioresistant tumors and those with involved lymph nodes, especially since the mortality can be kept low.

(To be concluded)

CASE 30191

DIFFERENTIAL DIAGNOSIS

DR. MERRILL C. SOSMANT†: If you do not object, I should like to reverse the usual order of procedure. Having been invited "downtown," I assume that the x-ray plays an important part in the diagnosis of this case. So I think that it is fair to start with the films alone without knowing anything about the history and see how far we can go by study of them. That is what I did with these films, which were sent to me the day before yesterday — I went over them thoroughly before I saw the history. It is not a completely honest or unbiased opinion because the roentgenologist knows simply from the way the films have been taken what they were thinking about; but perhaps it is as honest as any roentgenologist can be. Now let us look at the x-ray films.

*On leave of absence.

†Clinical professor of roentgenology, Harvard Medical School; roentgenologist, Peter Bent Brigham Hospital.

The lungs are clear — no sign of tuberculosis or tumor so far as I can see. With clear lungs like that we can disregard the rales and rhonchi that come up later. The left half of the diaphragm is elevated. That is the only abnormality that I see in the chest film. The heart is normal in size and shape. Nearly all patients suffering from heart failure have an enlarged heart. The two exceptions are angina pectoris, where the heart may be normal in size and shape, and Addison's disease, where the heart is smaller than usual.

The next three roentgenograms are plain films of the abdomen. One was taken face up, the second face down, and the third upright. They all show a mass in the left flank about 15 cm. in length and 12 cm. in width (Fig. 1). It is smoothly outlined with a peculiar pattern of air in its center. Apparently there is large bowel here, close under the left diaphragm, which rules out an enlarged spleen, since the colon is usually below it. Here is a large, irregular collection of air, which we must consider later. The upright film shows several fluid levels, but no evidence of obstruction. There is a mass in the flank, and the first consideration is the left kidney. Starting out with an intravenous pyelogram, according to the dates we have here, both renal pelvis are perfectly normal, so the mass is obviously not part of the left kidney. The ureters are also normal, with no evidence of obstruction. The bladder is well filled, also normal.

We have a large mass then, presumably with a necrotic center, in the left flank, and it is not kidney. Furthermore, the retroperitoneal shadows and the kidney shadow itself, as well as the iliopsoas shadow,

stand out quite well, so presumably it is not a retroperitoneal mass or it would displace the kidney more

The next x-ray, according to the dates on these films, is a barium enema. I am a little confused concerning the exact sequence of events. You can help me out here, Dr Robbins?

DR LAURENCE L. ROBBINS: The next thing actually done was not the barium enema, but a swallow of barium given at night, no films were taken and that explains why you see the collection of barium

mass and that leaves the small bowel as the point from which the barium enters the mass. There are numerous spot films, do they show the communication?

DR ROBBINS: No.

DR SOSNIN: Here is one that shows a mixture of fecal material and barium in the mass, as well as the small sausage shaped outline.

To summarize the x-ray films, we have a large tumor mass in the left flank that communicates with

FIGURE 1 Plain Film Showing Mass with Air Filled Necrotic Center

overlying the distal transverse colon at the time of the barium enema.

DR SOSNIN: That is the thing I could not understand. Here is the barium enema outlining the colon, which looks perfectly normal. The descending colon is here, lateral to the mass, and above the mass in the transverse colon. But in the mass there is some barium, which looks as if it might have come through a communication from the descending colon to the center of this mass, but the explanation Dr Robbins gave is satisfactory.

The next examination was a gastrointestinal series (fig 2), and now we see this large irregular, tube-like collection of barium in the left flank, corresponding exactly to the air-filled shadow we saw a moment ago. That cavity in the mass communicates with the gastrointestinal tract, presumably not with the colon. The stomach is pushed upward over the

small bowel and does not arise from the kidney. Presumably it is part of the small bowel itself, judging from the size and shape of this cavity here. There is no obstruction. It is in the left flank and is either part of the small bowel or directly connected with it.

Now let us go to the history and see if we can get any leads regarding what type of tumor mass it might be.

PRESENTATION OF CASE

A thirty-five year-old elevator operator entered the hospital because of pain in the left upper abdomen.

The history was rather unreliable and more or less contradictory. He was in apparent good health, except for an occasional stomach-ache relieved by soda, until two weeks before admission, when he

was seized by sharp pain in the left upper abdomen, which doubled him up. The pain lasted two or three days. Associated with the onset of his illness, or perhaps later, he developed chills and fever, marked anorexia and nausea. There was no vomiting. He had nocturia (one to three times), dysuria and urgency. He had two painful bowel movements with bloody stools during the week preceding admission. He apparently continued to work until the day of admission, when he had a recurrence of the severe

over the left costovertebral angle. Peristalsis was normal. The patient had pain in his abdomen when he coughed, but there was no rebound tenderness or masses. The prostate was of normal size, but boggy.

The blood pressure was 120 systolic, 75 diastolic. The temperature was 100.8°F., the pulse 76, and the respirations 16.

Examination of the blood showed a red-cell count of 3,500,000, with 65 per cent hemoglobin. The

FIGURE 2. Barium in Air-Filled Necrotic Mass.

pain in the left upper abdomen. No other information was available except that "he had lost a good bit of weight."

The patient broke his leg when he was seven years old, and at twenty-two he had a penile lesion.

Physical examination showed a well-developed, acutely ill, slightly stuporous man. A transient pleural friction rub was heard over the right apex anteriorly. There were a few fine basal rales on both sides, and occasional rhonchi at the right base. The left portion of the diaphragm was splinted. The heart was normal. There was marked tenderness and spasm in the entire left abdomen, most marked opposite the umbilicus and out toward the flank. Pain and tenderness were also elicited on percussion

white-cell count was 7400. The specific gravity of the urine was 1.006, with rare red and white cells in the sediment. The stools gave a +++ guaiac test. A blood Hinton test was negative. The blood nonprotein nitrogen was 21.5 mg. per 100 cc., and the protein 4.7 gm.; the chloride was 102 milliequiv. per liter.

A swallow of barium showed a normal esophagus. The stomach displayed a pressure defect and elongation. A small barium enema twenty-four hours later showed ready flow of the material to the cecum without delay. A large amount of gas and fecal matter was present, making the examination unsatisfactory. In the left upper quadrant a long, irregular mass of barium was seen, measuring 15

by 6 cm., which lay medial to the upper part of the descending colon and unattached to it. This apparently represented the barium swallowed twenty-four hours earlier. An intravenous pyelogram showed normal kidneys, ureters and bladder. There was a 15-cm. mass in the left midabdomen. Within the mass a large, air-containing, irregular cavity was seen. The fundus of the stomach was displaced to the left. A peculiar defect, thought to be due to an anatomic variation, was noted in the right ninth rib posteriorly. A gastrointestinal series showed a normal esophagus, but in the stomach there was a pressure defect, which seemed to be caused by a mass that lay behind and below it. This mass contained barium and apparently had no intimate connection with the stomach. The duodenum was normal, but the distal part was narrowed and displaced medially by the mass. It was thought that barium entered the tumor from the upper loop of the jejunum, but this was uncertain. The mass did not seem to cause obstruction. An x-ray film of the chest was negative except for increased density in the left lower lobe.

The patient's condition remained essentially the same. The temperature ranged between 100 and 103°F. Daily intravenous fluids and 2.5 gm. of sodium sulfadiazine were given. He had a moderate degree of rectal bleeding, but no vomiting. He was given two transfusions, and on the sixth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS (Continued)

DR. SOSMAN: There is a perfectly good possibility in a case like this that the histologic diagnosis could have been made from the stool, if the patient had been observant and had saved the specimen, since he may have passed some tumor. I assume that the chills and fever and the acute episode were due to the necrosis of the center of the tumor and subsequent discharge into the gastrointestinal tract. I do not believe that our medical students are taught to study the stools thoroughly enough. A great deal of information can be obtained from them. Only the pediatricians examine stools with great thoroughness.

The penile lesion brings up the possibility of gumma. A gumma in the gastrointestinal tract is extremely rare. I have seen two or three in the stomach. I do not believe that I have ever seen one in the small bowel or colon that was confirmed. Later on we find that the Hinton test was negative. It is an extremely sensitive test and it certainly should be positive if this were a gumma.

"There were few fine basal rales on both sides, and occasional rhonchi at the right base." These are the rales and the rhonchi that we threw away at the beginning of the exercise. We will leave them there.

Do the statements made in the abdominal examination mean that they did not feel a mass in the

left flank? The record seems to imply that tenderness and spasm had obscured the mass. The patient had a moderate anemia (3,500,000) and a normal white-cell count, and the urine was negative. The non-protein nitrogen was within normal range, and the blood protein was low.

I have already described most of the x-ray findings. The irregular mass containing barium, 15 by 6 cm. in size, which was apparently a false pocket in the tumor mass, I have described. I forgot to mention the small defect in the ninth rib posteriorly, but I think that is a congenital anomaly, sharp and clearly defined.

It is difficult at times to tell exactly where a fistula occurs. Barium runs around through the gastrointestinal tract with a great deal of variation or hesitation. It is sometimes impossible to say where the barium enters any given fistula or abnormal pocket. To sum the whole thing up, I think that this tumor mass in the left flank communicated with the bowel, in all probability with the small bowel. Then we have to try to line up all the various tumors that could occur in a thirty-five-year-old man with a very short history. Abscess, of course, is one of the first things to think of, but he was too young for diverticulitis. The usual diverticulitis of the colon occurs almost entirely beyond the age of fifty and is much commoner after sixty. There is no evidence of diverticulitis in the barium enema. If this man had been a farmer, or a man with similar occupational hazards, he would have been more likely to end up with actinomycosis. He had only a moderate fever, with a normal white-cell count, so that the diagnosis of abscess or inflammatory process is improbable. Tuberculosis is a possibility — a big broken down mass of tuberculous glands. It also would give more fever, and it is in the wrong location; usually it is in the right lower quadrant in the ileocecal region and frequently shows calcification, which I am unable to see in this particular case.

That leaves us, so far as I can think over the possibilities, with only a true neoplasm to consider — a neoplasm in a young man that had apparently developed rather rapidly. At least the patient had lost a good deal of weight, but the record does not say over what period of time. Neoplasm in a man of this age is usually sarcoma, arising in the bowel wall: a leiomyosarcoma, sometimes a lymphosarcoma or spindle-cell sarcoma or occasionally even an angiosarcoma. He passed a moderate amount of blood but had no extensive hemorrhage. We do not have to assume that this was a particularly vascular tumor. The red-cell count was only 3,500,000 — no marked anemia. Some authors have reported cases of melanotic sarcoma in the gastrointestinal tract, but the point of origin has always been doubtful. They are more probably metastatic from cutaneous melanomas. The carcinoids, rare tumors and are nearly apt to ulcerate. I throw

unusual possibilities. I should say that this belongs in the sarcoma group, probably originating in the small bowel, with an area of ulceration in the center of the tumor.

DR. BENJAMIN CASTLEMAN: Have you any preference among the sarcomas?

DR. SOSMAN: I have no preference. By taking the broader basis, I have more chance of being right. There is no reason to specify. Obviously it was a surgical problem, and the next thing to have been done was to explore the patient and see what could be done about it. The most we have done is to locate the lesion and to give an idea as to the type of tumor it might have been.

DR. CASTLEMAN: Are there any other suggestions?

DR. CHARLES G. MIXTER: Dr. Sosman ruled out the possibility of chronic or subacute abscess, the result of perforation, simply on the basis of the normal white-cell count and lack of fever.

DR. SOSMAN: That is true. An abscess in a man of this age is extremely rare. About the only reason for one would be perforation by a foreign body, such as a fishbone.

DR. MIXTER: That is what I was thinking about.

DR. SOSMAN: I have seen one in the spleen, — an abscess with a fishbone in the center of the abscess, — but this tumor mass had a thick wall, which I should not expect to see in pyogenic abscess.

May I ask how the X-ray Department interpreted the films?

DR. CASTLEMAN: They thought it was a malignant lymphoma.

DR. HORACE K. SOWLES: We discussed the case with Dr. Robbins the day before operation and came to about the same conclusion as that of Dr. Sosman, suggesting leiomyosarcoma or lymphoma as the most likely diagnosis. At the time of operation there was a large mass, involving the whole left abdomen, with a good deal of surrounding inflammatory reaction; it was bounded superiorly by the transverse colon and laterally by the descending colon and anteriorly was quite adherent to the anterior abdominal wall. In separating the anterior abdominal wall from this mass by finger dissection we went directly into an abscess cavity filled with mucopurulent material, and after a little more finger dissection, we brought up into the wound a loop of small bowel almost completely transected, with wide-open ends of small bowel, and tumor mass. It was possible, however, to isolate an afferent and efferent loop of the small bowel going into this area, to excise the wide-open portion, as well as a segment measuring 12 to 15 cm. on each side of it, and to do an end-to-end anastomosis of normal small bowel at that point. I did not see any particular object in trying to dissect farther, and I was afraid also that we might end up with a wide-open end of colon, which would not be easy to handle. We did the anastomosis, excised the area of small

bowel, put a drain in the lateral gutter through a stab wound and closed the incision.

CLINICAL DIAGNOSIS

Malignant lymphoma or leiomyosarcoma of small intestine.

DR. SOSMAN'S DIAGNOSIS

Sarcoma of small intestine.

ANATOMICAL DIAGNOSIS

Malignant lymphoma, lymphoblastic type, of small intestine.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The specimen we received contained a submucosal ulcerating tumor of the small intestine, about 3 or 4 cm. in length. It extended out into the mesentery of the small bowel as a extraluminal tumor mass measuring about 6 by 4 by 2 cm. Thus, a large extrinsic tumor and a smaller intrinsic one were present. On section they presented the uniform pinkish-gray smooth surface of lymphoma. Microscopically it proved to be of the lymphoblastic type, or what some prefer to call "lymphosarcoma."

DR. SOSMAN: Were there any palpable lymph nodes?

DR. CASTLEMAN: No nodes were found in the fat around the small bowel. It has been our experience that, in the majority of cases of malignant lymphoma of the stomach or intestine, the regional nodes are not involved.

DR. SOSMAN: That is the point I wanted to bring out: a solitary lesion in the gastrointestinal tract is susceptible of cure.

DR. CASTLEMAN: In cases of carcinoma we are likelier to find metastases.

DR. SOWLES: I might add that this man is reasonably sick. Postoperatively he had a certain amount of intra-abdominal infection and is probably going to develop a pelvic abscess, if he survives to that stage; of course, the prognosis is bad.

DR. CASTLEMAN: The prognosis of lymphoma of the gastrointestinal tract is fairly good if the tumor is completely removed surgically. It is only when the lymphoma has involved the lymph nodes that the outlook is bad.

DR. SOWLES: I doubt very much that we completely removed the tumor, although we did excise a goodly portion.

CASE 30192

PRESENTATION OF CASE

A fifty-four-year-old Italian waiter was admitted to the hospital complaining of epigastric pain.

The patient was apparently well until three months before admission, at which time he noted mild pain in the epigastrium, squeezing in character and coming on especially at night. It was inter-

mittent, lasting for a day or two and then disappearing for a week at a time. It was aggravated by meat and fried foods, and later by all solid foods; it was unaffected by the ingestion of milk or soda and somewhat relieved by bowel movements. About two weeks before entry into the hospital, the pain became much severer and almost continuous. It was associated with several bouts of chilly feelings and profuse sweating, occurring at night. On several occasions he was unable to retain fluid, which, after having apparently become caught at the level of the xiphoid process, was promptly regurgitated. There was no associated nausea. His bowel movements had been regular until he became constipated a few days before admission. He had lost 20 pounds of weight over a period of two months. He drank one pint of whisky a day until about five years previously.

Physical examination revealed a man complaining of abdominal pain but in no acute distress. The skin was soft, moist and warm. The tongue was heavily coated, and the breath foul. The lungs were clear. The heart sounds were distant. There was tenderness to deep pressure in the epigastrium, but no masses were palpable.

The blood pressure was 130 systolic, 90 diastolic. The temperature was 101°F., the pulse 108, and the respirations 20.

Examination of the blood revealed a red-cell count of 5,500,000, with 16 gm. of hemoglobin, and a white-cell count varying from 11,000 to 17,000, with 70 to 80 per cent neutrophils that showed a moderate shift to the left. The urine was negative. The stools were light brown and hard, they gave a +++ guaiac test on admission but subsequently became negative. The blood protein and non-protein nitrogen were within normal limits. The blood chloride was 98 milliequiv. per liter. Two bromsulfalein tests, at different times, showed 30 per cent and 15 per cent retention of dye after thirty minutes. A blood Hinton test was negative, as were a blood culture and tests for agglutinins against typhoid bacilli, Brucella and *Pasteurella tularensis*.

A gastrointestinal series revealed a 5-cm. area of esophageal narrowing above the cardia; the esophagus above this point was considerably dilated (Fig. 1). This area did not widen after the administration of amyl nitrite. Only a small amount of barium entered the stomach, and no defect could be demonstrated in the fundus. A barium enema revealed redundancy of the sigmoid. An esophagoscopy performed on the fifteenth hospital day revealed an area of reddening 4 cm. above the cardia. A biopsy of this area revealed acute and chronic inflammation, with epithelial hyperplasia and keratosis. Bougies (No 12 to No 24) were passed readily through the cardia, and subsequent x-ray examination revealed no residue in the esophagus, the barium passing readily into the stomach.

During his hospital stay the patient continued to complain of gnawing epigastric pain, which became severe on occasions. The temperature gradually rose to 103°F. At that time he appeared toxic, lethargic and somewhat incoherent. The pharynx was beefy red and two throat cultures revealed a few colonies of beta-hemolytic streptococci. Both leaves of the diaphragm were elevated. A pleural

FIGURE 1 Roentgenogram Showing Esophageal Dilatation

friction rub was heard over the right third rib anteriorly. A few sticky rales were audible at the right base, later replaced by numerous inspiratory and expiratory rales, associated with dullness and increased tactile and vocal fremitus. A roentgenogram of the chest revealed areas of density in the right lower and left upper lobes (Fig. 2). Because of the chest findings, sulfadiazine was administered in adequate dosage for an eight-day period, without apparent effect. The abdomen became increasingly distended, and the patient developed diarrhea alternating with periods of relative constipation.

Periods of elevation in temperature to 101 or 103°F. alternated with periods of almost normal

temperature. The chest condition showed improvement by physical and x-ray examination, but the patient remained lethargic and at times semistuporous, with only vague orientation regarding time and place. Neurologic examination revealed small irregular pupils that reacted sluggishly to light. The fundi were normal. Muscular coordination was poor. The abdominal and cremasteric reflexes were absent, and the deep tendon reflexes depressed. Vibration sense was diminished

dominal pain, also associated with shock. The pain was relieved by morphine and atropine, but the patient expired forty minutes later.

DIFFERENTIAL DIAGNOSIS

DR. WILLIAM B. BREED: I am sorry that I have so little time, because I had planned a nice wordy discussion of this case to cover up various spots of ignorance, and as you all know, the length of the discussion is inversely proportional to the accuracy.

FIGURE 2 [Roentgenogram of the Chest Showing Areas of Density in the Right Lower Lung

in the lower extremities. On lumbar puncture the spinal fluid was clear, under normal pressure and free of cells; the total protein was 73 mg. per 100 cc. On the thirty-eighth hospital day the patient had an attack of sudden severe pain that caused him to sit up and writhe about the bed, clutching his epigastrium. He was pale and sweating, his lips and nails blue, his pulse feeble, and his blood pressure 60 systolic. The abdomen, however, remained soft. Within a few hours he returned to his usual state of lethargy. Four days later the stool was found to be tarry, and the guaiac test was + + + +. On the following day, his forty-third in the hospital, he suffered another severe attack of ab-

But now I am forced to gird my loins and be more accurate than I had planned. When one is given a case that involves so many different structures in the body, such as the esophagus, the lungs, some viscus presumably under the diaphragm and possibly the central nervous system, it is important to try to hit on one pathologic process that will account for all of them. Of course the granulomas, such as syphilis and tuberculosis, stand first on such a list. The patient had negative blood Wassermann and Hinton tests, and also a spinal fluid that appears to have been negative. I am going to get, I hope, some information from Dr. Robbins. Perhaps he will help clarify the chest

situation, which is quite hopeless to my mind. In trying to explain these widespread lesions, the well known standby of lymphoma comes into prominence.

I shall talk to Dr Robbins about the x-ray films, or perhaps I shall just listen.

DR LAURENCE L. ROBBINS This is the chest film showing areas of increased density scattered throughout the right lower lung field, with a few in the left lung. I do not know the answer in this case, but I think that the patient had some reason to have changes in the chest because of the obstruction in the esophagus.

DR BREED This report is a little contradictory, since it says, "A roentgenogram of the chest revealed areas of density in the right lower and left upper lobes."

DR ROBBINS I did not put up the lateral film in which there are a few areas of increased density in the left upper lobe.

The esophagus is dilated, as one can see from this film. Without any question the process was of considerable standing because, in addition to the size, there were fluid and food in the esophagus. This other film was taken later, after the bougienage, when there was no delay at the cardia. When I examined him the lower esophagus seemed to be funnel shaped and looked like cardiospasm to a certain extent. The esophagus did not change with amyl nitrite, and at no time could I be sure of a defect in the stomach, although I did raise the question on the chest film whether there might have been something wrong with the fundus.

DR BREED That does not look like a metastatic process in the lung?

DR ROBBINS It is not characteristic of it.

DR BREED I am a bit disturbed because the record says that there was esophageal narrowing 5 cm. above the cardia.

DR ROBBINS It is not particularly clear in these films, but if this is the cardia there is an area of narrowing about 5 cm. above it.

DR BREED Did you call it cardiospasm?

DR ROBBINS I raised that question and the other alternative that one always worries about in that area.

DR BREED Dr Edward B. Benedict apparently esophagoscoped this man, found a red mucosa and did a biopsy, which showed acute and chronic inflammation with epithelial hyperplasia and keratosis. What does that mean to you, Dr Castleman?

DR BENJAMIN CASTLEMAN Only that there was some keratosis, which could have been the result of chronic inflammation.

DR BREED I think it is extremely unlikely that one diagnosis can explain the findings in the esophagus and the presumable lesion underneath the diaphragm, and I doubt that the correct diagnosis will be even mentioned before Dr Castleman tells us about it.

Certainly the patient had a reasonably rapid and progressive toxic or septic process, with fever and epigastric pain, but with no obvious peritoneal irritation. On examination during all this time, his abdomen was said to have been soft. There was deep tenderness, which is not to my mind particularly significant. Looking at these x-ray films now, I think that this process could perfectly well have been a reflection of some sort of disease under the diaphragm.

Let us assume that the patient had cardiospasm or some other benign constriction of the esophagus above the cardia that was dilatable with bougies. I am going to assume that without going into detail, and I also believe that his main difficulty was under the diaphragm in the region of the liver. He had had a certain amount of alcohol for thirty years, and he exhibited some evidence of liver dysfunction. Possibly he had a hepatoma in a cirrhotic liver. Let us see if that adds up to anything. That would explain a good many of the symptoms. It would also explain, I believe, the lesions above the right diaphragm. It would not account for his sudden death, which I am unable to explain. The story gives one the impression of a ruptured vessel without any evidence of peritoneal irritation on examination, this seems to be an unlikely explanation. A subdiaphragmatic abscess or abscess in the liver, amebic or otherwise, might explain the picture. I believe that the neurologic findings were probably terminal and that he did not have actual disease of the nervous system. Certainly nothing of that nature is demonstrable in the record, and the findings on physical examination could have been preterminal.

In trying to arrive at a diagnosis it is a great mistake to guess too much. I am prepared, however, neither to make a diagnosis nor to guess the diagnosis. I merely say that I think the primary lesion was probably in or about the liver and that it probably was some sort of malignant process, not primarily one of infection, a hepatoma in a mildly cirrhotic liver is all right, but it is pure guesswork. One could name three or four different mortal diseases of a malignant nature, but I am not prepared to guess.

Do you want me to be more specific?

DR CASTLEMAN Yes.

DR BREED Do you want me to make one diagnosis?

DR CASTLEMAN That would be preferable.

DR BREED It would be pure guess, and I am not sure it is legitimate. Did he have one or two diseases? Is that a fair question?

DR CASTLEMAN Not exactly, but I am willing to say that he had two diseases that were related.

DR BREED Since I am pushed into a corner and have to guess, I shall say that he had a hepatoma secondary to a cirrhotic liver.

DR EARLE M. CHAPMAN I secretly enjoyed Dr Breed's sweating. He was in exactly the same posi-

tion that I was in. I was completely puzzled and could not make a diagnosis. Dr. Paul D. White, who was previously on service, thought of a number of possibilities; and he, too, was wrong. Dr. Gerardo M. Balboni, who had been taking care of the patient for a long time, was convinced that he had Korsakoff's disease, with cirrhosis of the liver. We did not have much else to go on. Dr. Breed was astute in placing the disease below the diaphragm because Dr. Balboni and I put it above.

DR. BREED: But he died, do not forget that.

DR. CHAPMAN: He was going down hill so fast that we asked the Surgical Service to see him; they declared that he did not have a surgical abdomen.

of the symptoms. It could also explain the agonizing abdominal pain with death within a few hours.

DR. BREED: You would not be willing to accept cirrhosis alone in this picture?

DR. JONES: So far as the pain and fever are concerned, yes; but I do not believe that cirrhosis was the whole or the true story.

The difficulty in swallowing is the other curious part of the story. One thing might be mentioned in defense of Dr. Benedict, who did the biopsy. It is frequently impossible to obtain an adequate specimen by esophagoscopy, owing to the presence of an area of inflammation just above the actual site of trouble, which may be carcinoma. Dr.

FIGURE 3.

At the first attack that is described he had pain. Dr. Madelaine Brown examined him neurologically, and during this examination he had a convulsive-like seizure, which was extremely dramatic. Five minutes later he was in shock, holding his abdomen and writhing in pain. We did not know what was wrong with him. He survived that attack, but died in a subsequent attack five days later.

DR. CASTLEMAN: Dr. Jones, have you any suggestions to offer?

DR. CHESTER M. JONES: I am sure that I cannot make a diagnosis, but from the facts given us there are certain things one has a right to mention.

In the first place one sees, although infrequently, acute abdominal pain with cirrhosis of the liver—so acute that the question of surgical intervention arises and severe enough to require morphine, a drug that can precipitate a fatal outcome. It is perfectly fair to suspect that this man may have had cirrhosis of the liver. That would account for a great many

Robbins also had to hedge on the x-ray interpretation of cardiospasm. The diagnosis of carcinoma ought to be seriously considered, and I gather that Dr. Robbins did consider it as a possibility.

Two other points are worthy of mention: the patient had evidence of a hepatic disorder and he was an Italian who had used a reasonable amount of alcohol. Cirrhosis is not an uncommon finding in this particular group. In addition, there was some dye retention, which bears out that possibility.

The bleeding is also interesting and has not been explained. It is quite possible that the patient had a carcinomatous lesion from which he was bleeding, or he might even have had varicosities just below the cardia, rather than above, as a cause of bleeding.

The story of mental confusion and the neurologic findings,—the absent reflexes and the diminished vibration sense,—the very red, sore mouth—which was certainly not due to a streptococcal infection—and the clear spinal fluid with definite ele-

vation in protein, all could go with deficiency disease. This would fit in with a Korsakoff's syndrome.

I think Dr. Breed is absolutely correct in refusing to be drawn into a flat diagnosis. He has shown good judgment. But I believe that cirrhosis was in the background and that there might have been a malignant process in addition, superimposed or adjacent to it.

CLINICAL DIAGNOSES

Alcoholic cirrhosis of liver?

Korsakoff's psychosis.

Carcinoma of stomach?

DR. BREED'S DIAGNOSIS

Cirrhosis of liver, with superimposed hepatoma.

ANATOMICAL DIAGNOSES

Epidermoid carcinoma (Grade III), of esophagus, with metastases to mediastinal and retroperitoneal lymph nodes, pancreas and esophagus.

Perforation of pancreatic metastasis into cardiac end of stomach.

Massive hemorrhage into stomach.

Lipid pneumonia.

Multiple foci of degeneration in cerebral cortex.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The autopsy on this man showed a large mass in the abdomen that apparently invaded, or was part of, the body and tail of the pancreas; this mass had perforated into the stomach (Fig. 3). At the time of the autopsy we thought that that was the whole story. The stomach was filled with a huge cast of clotted blood.

Later, however, in the esophagus, 5 or 6 cm. above the cardia, we found an ulcerated lesion measuring 3 by 2 cm. that had infiltrated the wall; about 2 cm. above that was a similar but smaller lesion, and there was a third one above that. These three esophageal lesions, as well as the mass in the abdomen, proved to be epidermoid carcinoma. The tumor was therefore primary in the esophagus and not in the pancreas, and the "pancreatic mass" proved to be a large group of cancerous retroperitoneal lymph nodes that had invaded and replaced the body and tail of the pancreas.

That does not explain the lesions in the lung, which, grossly, were moderately firm and believed to be carcinomatous metastases. These proved to be areas of oil-aspiration pneumonia or lipid pneumonia, which is often found in patients with cardio-spasm or other lesions in the esophagus. The man had probably been taking a lot of mineral oil, and during the course of time appreciable amounts of oil had gained access to the lungs.

NEW MEDICAL FOOD REGULATIONS

A POINT system of food rationing has now been in operation for well over a year, having been inaugurated on March 1, 1943. The fact that our nation continues to eat, and to eat moderately well in addition to supplying foods to other countries, seems to indicate that the system works in a reasonably satisfactory manner. It has its faults and its inadequacies; abuses have crept in and black markets have flourished, human nature being what it is, yet we have kept ourselves not only free from want, but well nourished.

On account of the obvious need for special dietary consideration on the part of certain institutions and

population groups, the director of the War Food Administration requested the National Research Council in April, 1943, to appoint a committee of physicians to advise concerning the extent of these special needs and the best method of meeting them. The Subcommittee on Medical Food Requirements, within the Division of Medical Science of the National Research Council, under the chairmanship of Dr. William D. Stroud, of Philadelphia, resulted, and its recommendations were published in the October 16 and 23, 1943, issues of the *Journal of the American Medical Association*.

As of April 6, 1944, thirteen months and six days after the inauguration of point rationing, the Office of Price Administration adopted the recommendations of the subcommittee, practically without change! For over a year each local board, each state and each region have solved their own food-rationing problems as they apply to the care of the sick, and in many instances have devised their own more or less complex, more or less satisfactory systems of operation. The mills of the gods certainly grind exceeding slow, whatever the quality of their meal.

In June, 1943, at the request of the District Rationing Officer, the president of the Massachusetts Medical Society appointed an advisory committee to aid in the medical aspects of food rationing. The Boston district, which originally extended westward to Worcester, was enlarged in October to include the entire state, and during the winter was merged with the New England Regional Office, by some sort of phagocytic process. There has been a tendency, consequently, to enlarge the usefulness of the Massachusetts committee, since Rhode Island is so far the only other New England state with a medical advisory committee.

The new regulations, adopted at long last by the Office of Price Administration, are more drastic than the homespun principles under which the district has functioned for nearly a year. The list of diseases that automatically rate extra rations is a short one, consisting only of diabetes mellitus, active tuberculosis, chronic nephritis of the nephrotic type, cirrhosis of the liver, severe hepatitis, chronic suppurative diseases, severe burns, gastrointestinal lesions and pregnancy for extra meats, fats and oils, and diabetes and active tuberculosis for extra allot-

ments of processed foods. All other requests must be approved by the New England Regional Office — an extra hazard for those physicians who still ask additional allotments for their patients with gall-bladder disease, heart conditions of all types, obesity, anemia, pneumonia and polyneuritis.

Furthermore, with the recent lowering of point values and the virtual abandonment of rationing for many foods, it seems likely that little will be needed for anyone in the nature of extra concessions.

FREDERICK II OF HOHENSTAUFEN AND HIS FAVORITE SPORT

A CULTURED, gifted, thirteenth-century pioneer in medical education and economics, a fighting king, the founder of the University of Naples in 1224 (the first school in Europe to be established by a charter), a student of mathematics, natural history and philosophy, a man with an absorbing passion for the now nearly extinct sport of falconry and the writer of a book on the subject, composed in the critical spirit of modern science — such was Frederick II of Hohenstaufen, Holy Roman Emperor, King of Sicily and Jerusalem.

His treatise on falconry is one of the most important zoological works of the Middle Ages. The original text, compiled by himself, was lost in a battle before Parma, but a devoted son, Manfred, prepared a revision of the first two books, the basis for the printed editions that followed. Fortunately at least six other contemporary manuscripts of the complete work are known, and six more of the two-book manuscript. There have been four printed editions of the first two books, but none of the entire work until the one recently issued by the late American ophthalmologist, Dr. Casey A. Wood, and his secretary, F. Marjorie Fyfe.¹ After his retirement from practice in Chicago, Wood spent years in Europe probing into and comparing the texts of every manuscript of this book that he could find.² In the University Library at Bologna he discovered the fullest text, and in the Vatican Library at Rome the one most superbly illustrated. Wood's translation covers over four hundred large pages, an indication of how detailed was the study of Frederick II. The king recorded for the first time such observations as the pneumaticity of the bones, the form of

the sternum, the mechanical condition of flight, and migrations. Frederick experimented on the artificial incubation of eggs. The scientific world owes much to Wood for his clear rendering of the Latin manuscripts. By publishing the whole work, much new material has been added, particularly on the use of the lure, on the training of falcons in a cast, on crane hawking with gyrfalcons, on heron hawking with sakers and on hawking at the brook with the peregrine falcon.

To Wood's translation of *De Arte Venandi cum Avibus*, Walter Schlüter has added a chapter on falconry in modern times. Falconry was a favorite sport of all classes in Europe up to the time of the French Revolution. It has survived in a few areas. In England there are examples of family falconers running through many generations, such as the Fleming family of Barochan Tower, who, up to recent years, were still flying falcons in England and in India. Holland, France, Germany, Australia and America all have small but active centers of falconry, but the great days, when Frederick II had hunting lodges scattered throughout the mountains of Sicily and southern Italy, in places all too familiar today in our daily news, are long past.

Frederick has other claims to fame besides his scientific book on falconry. He gave to Sicily a remarkable code of laws, promulgating a regulation of the practice of medicine, the first elaborate work of its kind. To Salerno, the great medical school of his day, he granted the exclusive right to confer the license to practice medicine in the whole kingdom, and his stipulation for the length of medical studies has a modern ring: five years, plus one year of practical work under the guidance of an experienced physician, corresponding to one year of internship. A second postgraduate year was taken by surgeons, similar to a residency. Are we less wise than Frederick II in curtailing medical education in wartime, whereas, he, who lived in a continuous state of war, provided five or six years for medical training? Possibly the twentieth century has something to learn from the thirteenth.

DEATH

PARLOW — George G. Parlow, M.D., of Wareham, died April 20. He was in his seventy-fifth year.

Dr. Parlow received his degree from the College of Physicians and Surgeons, Boston, in 1905. He was a member of the Massachusetts Medical Society and the American Medical Association.

CORRESPONDENCE

AN EXPRESSION OF APPRECIATION

To the Editor: National Hospital Day is Friday, May 12. This year in bringing hospitals to the attention of the public, emphasis is being placed on what the hospitals are doing in keeping our civilian population well and at work during the third year of the war. We believe that we are making a vital contribution to the war effort, and that the public should be informed regarding some of the difficulties being encountered in the operation of our institutions.

The committee arranging for the observance of National Hospital Day in Massachusetts was unanimous in requesting that I express to the members of the Massachusetts Medical Society, through the *New England Journal of Medicine*, our very real appreciation of the contribution the doctors on our hospital staffs are making in keeping our hospitals operating. Many who had retired from active practice have come back to work long hours. The rest of the doctors have greatly increased their burdens in order to give adequate care to our communities. As president of the Massachusetts Hospital Association, in the name of the administrators of our hospitals, I wish to thank the members of the Massachusetts Medical Society for the invaluable contribution they are making to the continued operation of our institutions. Without their devoted service, it would be impossible to keep our doors open to the public.

GEORGE A. MACIVER, President
Massachusetts Hospital Association

BOARD OF REGISTRATION IN MEDICINE

To the Editor: Recently a member of the medical profession of Massachusetts was quoted by the newspapers as saying, in regard to certain matters concerning the Board of Registration in Medicine, that the Board had been "a sort of plague spot for years." The statement did not say what sort of plague spot nor how long it had been a plague spot, but the quotation went on to state that the conditions, however, had been improving. This also was not made clear and in view of the fact that the Governor had seen fit to "oust" three members of the Board, according to newspaper reports, one wonders in what the "improvement" had consisted. The situation has been left in a very unsatisfactory state. The Governor is reported to have said "the less said about it the better." The Attorney-General is reported to have said that he found no ground for criminal action. This may be taken to mean that there was no violation of the letter of the law.

I am writing because I think the medical profession and the public have a right to know more about the background of the situation and because I know nothing about the specific facts in the late incident, although I am familiar through years of experience with the work of the Board. Therefore, I write impersonally and I shall attempt to point out the framework of reference within which the discussion should take place.

The duties of the Board lie, in general, in two fields—the licensing and the unlicensing of physicians. The former is usually done after examination, although occasionally, in the case of a physician whose license had been revoked by the Board, without examination, but a license is revoked only after a hearing, as provided by law.

What qualifications does the law set for performing the first duty, which includes the setting of an examination that shall be practical in character and sufficiently thorough to test the qualification of the candidate for the practice of medicine? Substantially these: the candidate for appointment shall himself be licensed by the Board and shall be engaged in the practice of medicine for ten years, but he shall

not be connected with a medical school. This last phrase excludes from the Board the physicians who are likely to know how to set an examination and the examinations are, therefore, more likely to be an unsatisfactory test than if they were given by someone familiar with teaching. Is it going too far to say that the law sets a premium on not knowing how to set an examination?

What of the ten years of practice? Of what value is that? Probably it impairs the competence to set an examination, for the farther the candidate is from his own student days the less likely he is to be familiar with the technique of that procedure. But it is in the unlicensing of physicians that the ten years of experience in practice may be invaluable. The board member has had an opportunity to experience the problems met in actual practice and is in a better position to exercise discretion in deciding whether a physician has been guilty of "gross misconduct in the practice of his profession."

It would be interesting to go into the history of that disqualification—connection with a medical school—and find out why it was introduced into the law and why it has not been deleted when in the opinion of many persons it has no present usefulness and may actually prove to be an obstacle to attaining one of the purposes for which the Board exists. Thus the first difficulty is with the law.

The second difficulty is of a different character: not all governors take the Board seriously. Again and again physicians have been appointed to positions of trust, when consulting the records of the Board might have indicated the impropriety of the appointment. It is not a question of asking the Board or its chairman or its secretary for recommendation or disapproval. It is asking for the record, the facts. Has the candidate ever been reported to the Board for any alleged impropriety in practice, what was the nature of the complaint, and what were the findings of the Board?

Appointment to the Board carries an inconsiderable salary but for some physicians prestige is enhanced. Too often the appointment is in payment for some political debt or as a reward for medical services to the community (or to the executive) faithfully performed. The law says that the candidate shall have been engaged in practice for ten years, not for one hundred and ten years, and the candidate should be young enough to have vigor to carry through carefully and conscientiously what some persons may regard as the chore of evaluating and grading justly six, seven or eight hundred examination books each year. Although the work done at ten Board meetings a year may be of great importance, it is an incomparably lighter burden than properly grading the examination books. Rarely does the question seem to be asked, Has the candidate fitness for setting examinations, understanding, firmness, wisdom, integrity, a judicial mind?

At one time there were on the Board of Registration in Medicine in Massachusetts, two members who had had cerebral hemorrhage. The presumption was against these men being able to act with proper discrimination if subjected to stress, or in cases involving delicate weighing of evidence. This brings us to the third difficulty.

Under the statute, the Board may under certain circumstances exercise its discretion, which means that individual members must exercise their discretion. If the executive has appointed indiscreet persons, the system breaks down under pressure. In the nature of things stress is inevitable. By no possible effort can the procedure be made mechanical. On the one hand there are the welfare, happiness, and lives of the citizens of the Commonwealth, all human beings; on the other hand are candidates for licensure, eager for practice, with various degrees of qualification, also human beings. Judgment concerning qualification for practice requires a fine discrimination, a scalpel wielded with intelligent skill, not a blunderbuss fired in all directions.

The problems presented by the Board of Registration in Medicine are in part problems for the medical profession. The question that I should like to bring home to every physician in Massachusetts who is really interested in upholding the high ideals of the profession by trying to realize them is, What have you done to change conditions in this state so that no one can say with justice that we have in Massachusetts a plague spot?

THE HISTORY OF THE DISCOVERY AND ISOLATION OF THE FEMALE SEX HORMONES

GERHARD J. NEWERLA, M.D.*

WALTHAM, MASSACHUSETTS

I SWEAR by Apollo, the physician, and Aesculapius, and Hygeia, and Panacea, and all the Gods and Goddesses . . . [that] I will not give a woman a pessary to cause abortion." Thus reads the Hippocratic Oath, to which every physician swears, and thus for the first time in medical ethics the Greeks recognized the sanctity of motherhood. Yet even in the Greek civilization of Hippocrates abortion was not illegal or criminal, but was merely left to the midwives, who also officiated at births and brought together suitable matrimonial candidates.

The phenomena of menstruation and pregnancy have been known to man as long as has the human race itself, but their true nature and mechanisms were not understood until fairly recent times. The word "menses" is indirectly derived from the Greek noun meaning "moon." The ancient Greeks used it to describe the monthly flow from the vagina. They regarded the menses as effect of the moon on the female organism and as a periodic cleansing of the uterus.

According to the *Ayurveda* by Susruta,¹ of India (ca 1400 B.C.), the ancient Hindus regarded the menstrual flow as an "impurity" of the seven body elements. Impregnation was considered to be easiest during the menstrual flow, and the fetus was believed to be formed by the union of the male semen with the "fiery" menstrual blood. The sex of the fetus was presumably determined by the preponderance of either the semen, which produced a male fetus, or the menstrual blood, which produced a female one. If both elements were equivalent, a hermaphrodite was created. The Egyptians of the era of Ptolemy (ca. 300 B.C.) already knew means by which to induce conception and increase fertility, and could diagnose pregnancy at a comparatively early stage.¹

The true physiology of the ovaries, however, remained unknown until the seventeenth century. Theodore Kerckring² (1643-1693), of Amsterdam,

was one of the earliest to state that the "ovum" — as the ovarian follicle was then called — was expelled by the onset of menstruation or by sexual excitement. This view was disproved in 1843 by Ritchie,³ who demonstrated that menstruation and ovulation were dependent on each other and that ovulation determined menstruation. Yet it was not until 1927 that Corner⁴ proved that even menstruation may occur without ovulation. Heijdenrijk Overkamp⁵ (1651-1692), a contemporary of Kerckring, believed that the "ova" — that is, follicles — formed a substance that passed into the general circulation. The Frenchman Nicholas Venette⁶ (1633-1698) called this substance "the spermatie vapors" and believed that it produced menstruation after entering the systemic circulation. François Mauriceau⁷ (1637-1709) was the first to suggest that conception was not dependent on menstruation, and Bischoff⁸ in 1844 proved that the ova matured periodically and independently of coitus. The concept that the primary function of the uterus is pregnancy and that menstruation is merely an indication of the thwarting of this function is therefore of modern origin.

It is of historical interest to observe that some of the earliest indications of the variability of the abnormal female sex characteristics that today are recognized as embryologic or endocrine disorders were expressed in the artistic creations of ancient and medieval origin. At least two types of mixed-sex personalities can be detected in the classic sculptures and paintings: virilism and hermaphroditism. Antique statuary unearthed by excavations in Asia Minor, Greece and Italy show these two distinct types; for in those times it was the acme of sculptural endeavor to adorn men with feminine characteristics, and women with those of men. Perhaps the best-known example of virilism in women is the famous statue of Psyche, the mistress of Eros, now preserved in the Museum of Naples. This figure exhibits small and flat breasts on a wide masculine chest and a long body of straight lines terminating in a small pelvis. Hippocrates describes in his

*Instructor in pharmacology, Middlesex University School of Medicine.

Epidemics two women with marked facial hirsutism during the menopause.⁹ Many artistic works and even modern side shows still attest to the prevalence of this curiosity. Archaeological research indicates that the inhabitants of the island of Cyprus in the eastern Mediterranean in antiquity worshiped a bearded female deity, part of a cult imported from the East, but no sculptures portraying this goddess have been unearthed.¹⁰

The hermaphroditic statues of the ancient Greeks were frequently sculptured after living models, but some were based on an ideal concept that incorporated the most aesthetic features of both the male and the female bodies. The best examples of this natural hermaphrodite statuary are preserved in the Villa Albani in Rome, where the art-loving Cardinal Albani (1692-1779) assembled an exquisite collection during the eighteenth century; in the State Museum of Berlin; and among the art objects in the Museum of Naples, from those that were excavated at Herculaneum, the city destroyed together with Pompeii by the eruption of Vesuvius in 77 A.D. These hermaphrodites possess a predominantly female body contour adorned with male genitalia.

The best sculptures of natural hermaphrodites were unearthed in the Necropolis at Myrina in Asia Minor. These statuettes, which are of terra cotta, display composite characteristics of both young men and young women. They show a delicately rounded neck and generous fatty pads, especially on the buttocks, hips, thighs and pubes. The abdomen is slightly protruding, but the face shows a delicate and gracious feminine expression. The well-formed breasts appear small, and the extremely small external genitalia are those of the male.

The masters of the Renaissance likewise preferred females suggestive of hypogonadism. The portraits by Botticelli (1447-1515) depict women with small breasts, a long neck and long extremities, as in the paintings "Truth and Repentance" and "The Birth of Venus," now in the Art Galleries in Florence. A similar trend is seen in the Flemish brother-painters Van Eyck, who lived in the fifteenth century. Jan Van Eyck's "Eve" and "The Love Spell," by one of the pupils of the Van Eycks, now in the galleries of Leipzig, are examples of this trend. The Museo de Prado in Madrid has a painting of the crucifixion of the "bearded" Saint Wildegeforth. The Spanish master Ribera (1588-1652) portrayed himself together with Madelaine Ventura, also a bearded woman, who is shown nursing an infant.¹¹

Perhaps the earliest medical conception — or rather misconception — of the value of glandular products found its expression in organotherapy — that is, in the medicinal use of various animal and human tissues and excretions for the express purpose of deriving certain specific physiologic effects from their use. In fact, *materia medica*, and especially therapeutics and endocrinology, have sprung

from this type of remedial custom of primitive races and ancient civilizations. The primitive tribes had already observed how some animals — and among these even the herbivorous cow — swallowed the placenta after their young had been born. It was therefore logical to assume that placental tissue would arrest post-partum hemorrhages, stimulate milk secretion and even cure sterility. The long survival of primitive organotherapy was due primarily to popular superstition and a belief in magic powers, and had no scientific basis. One reads today with amazement of such customs as eating one's enemies or the organs of certain animals to acquire their particular qualities.

The rationale of medieval substitution therapy was well formulated by Thomas Vicary¹² (1490-1561) when he wrote in 1548 that "in what part of the body the faculty which you would strengthen lies, take the same part of the body of another creature in whom the faculty is strong, as a medicine." Organotherapy has prevailed until recent times, and even today is practiced to certain degrees, although it has become limited to the "glandular pills" and "desiccated polyglandular" nostrums heralded by modern superadvertising campaigns of exploiting patent-medicine makers. Landouzy¹³ in 1898, at a time when the so-called "invigorating" effects of glandular concoctions were blatantly publicized, and when the real functions and actions of the glands of internal secretion were beginning to be scientifically investigated, suggested "opotherapy" as a substitute for the old word "organotherapy" — perhaps to avoid the evil connotation of the latter word, or perhaps because he realized the secretory function and nature of these glands. The name "opotherapy" Landouzy derived from the Greek nouns *οπος*, "juice," and *θεραπεια*, "treatment," but this word never found scientific or popular favor.

Dana¹⁴ in 1916 conferred the title "Author of Opootherapy and Endocrinology" on Joannes Ursinus,¹⁵ a French physician-poet, who wrote *Protopopoeia animalium aliquot* in 1541. This is an elegiac poem in which Ursinus describes the remedial value and uses of seventy-five animal preparations. Ursinus thus by more than a century preceded Johann Joachim Becher¹⁶ (1635-1682), whose *Parnassus medicinalis illustratus*, written in 1663, dealt with the animal, vegetable and mineral remedies of his time. This remarkable book, written much in the style of the Health Rules of Salerno, both in verse and in prose, contained in four parts more than one thousand pages and twelve hundred illustrations. It mentioned forty animal and twenty-five human substances that supposedly had some remedial value.

Limiting organotherapy to the specific employment of the excretory sex products of the female, either animal or human, which, as is known today, contain certain hormonal ingredients, one finds a

protean assortment of these in ancient and medieval — and even modern — therapeutics. A few of the more repulsive substances and the blatant claims for these remedies will be mentioned.

According to the *Papyrus Ebers*, which is generally dated at about 1550 B.C., the ancient Egyptian pharmacopoeia contained over one hundred groups of preparations, and at least forty of these were animal or human excretions.¹⁷ For instance, the urine of a spouse who had remained faithful to her husband and had known no other man was a remedy for sore eyes. Herodotus¹⁸ (ca. 500-424 B.C.) tells the story of the Egyptian king Phoron, the son of Sesostris, conqueror of Egypt, who had to search diligently for ten years before he could obtain this medicine. He had tried the urine of his wife and of many other women without results. At last he succeeded, married this woman and burned all the others to death — quite a commentary on the morals of those times. Among the ancient Hindus, propagation began with religious ceremonies. Immediately preceding intercourse, an ointment prepared from the dried and powdered penis of a bear and the perirenal fat of a tiger (the kidneys were then regarded as the semen-producing organs) was applied for "prompt action." Bourke¹⁹ relates many similar tales.

Among the ancient Romans the *Natural History* of Cajus Pliny the Elder²⁰ (23-79 A.D.), who inveterately disliked all physicians, tabulated more than two hundred and fifty remedies of animal or human origin, as compiled by four hundred and seventy-three earlier authors. Pliny²⁰ spoke highly of the medicinal virtues of menstrual blood, not only for the cure of certain diseases but also for killing insect pests at a distance and for quelling storms at sea. Yet it would spoil wine, and dogs licking it would become mad.

In the Middle Ages the Dominican monk Albertus von Bollstädt²¹ (1193-1280), later Bishop of Regensburg, better known as Albertus Magnus, taught at the universities of Paris and Cologne. While lecturing at Paris he recommended powdered testes of hogs in wine for men with poor sexual powers, and powdered uteri of hares, similarly prepared, to render sterile women fertile.²¹ Rondelet,²² of Montpellier (1507-1566), is credited by Rolleston²³ with a prescription advocating the dried powder of placenta for the uncomplicated expulsion of the retained secundines after delivery.

Even today such substitution therapy still prevails in the less civilized countries of Europe. The Serbs, for instance, believe that nothing is better for the treatment of impotence than a few dashes of the urine of a pregnant mare, taken in a glass of water.

In this connection should also be mentioned the rejuvenation fad of three decades ago. Rejuvenation in women is even more problematic and uncertain than that in men. The observation of

Steinach and Holzkehn²⁴ that roentgen rays applied to the female pelvis act similarly to vasoligation in males, and that although harming the generative functions of the ovary they produce a proliferation of the ovarian interstitial cells, has not been found true. Zondek²⁵ criticized this theory by stating that Steinach disregarded the fact that during the menopause the follicles are destroyed and that only certain connective tissues remain, holding that not enough interstitial cells that can be stimulated are left. He also attacked as unfounded the suggestion of Liepmann²⁶ that hysterectomy can produce rejuvenation by reason of ligation of the ovarian tubes, and concludes: "On the whole, therefore, the attempts at rejuvenation are hardly adapted to induce an actual renaissance of aged human beings. Such endeavors cannot, indeed, be assumed to harmonize with nature's plan of organization."

Although the existence, not necessarily the function, of the testes was known to ancient civilizations because of their external location and easy accessibility, that of the ovary was often not even suspected. Herophilus of Alexandria (ca. 300 B.C.) is credited by Galen²⁷ with the anatomical discovery of the uterine tubes — or *meati spermatici*, as he called them — and with the "female testes," or *testes muliebris*. He also believed that the male and female semens were transmitted through the "spermatic vessels" and that the tubes passed from the "female testes" to the neck of the bladder, a conception later disproved by Galen.

The Greeks of the Hippocratic era did not know of the existence of the ovaries and thought that the "female semen" was produced as the vaginal secretion during coitus.¹ They believed that conception occurred most easily during the menstrual flow, when girls were conceived, whereas the period immediately after the flow was optimal for the procreation of boys. In this respect their views coincided closely with those of the ancient Hindus. Athenaios of Attalia in Cilicia (ca. 70 A.D.) considered the "female testes" as well as the male breasts as simple symmetrical appendages.¹

Castration of women was already practiced by the ancient Hindus, and Tillmanns relates that even the aboriginal Australian tribes performed operations for artificial hypospadias and ovariectomy to produce impotence and sterility among the unmarried members of their tribes, thus facilitating unproductive sexual intercourse among them.¹

For nearly fifteen hundred years after Herophilus there was little advance in the anatomical knowledge of the female gonads. The discovery of Herophilus was probably lost in the destruction and fire of the great Library of Alexandria by the Arabs in 640 A.D. Galen reigned supreme, although his anatomical concepts were based to a large extent on fancy. So great was the authority of C

Henri de Mondeville (1260-1320) exclaimed with reckless courage "God did not surely exhaust all His wisdom in the creation of Galen."²⁸

The *De Fabrica*, by Vesalius²⁹ (1514-1564), gives an account of the irregular surface of the "female testes," as the ovaries were still called. The name "ovary" originated in 1621 when Fabricius ab Aquapendente³⁰ (1537-1619), who believed that the ovaries contained the "female semen," introduced this name after observing the ovaries of hens. "Ovary" was first applied to human beings in 1667 by Niels Stensen³¹ (1648-1686), who suggested that the vesicles or "blisters" in the female testes were the ova. Also known as Nicolaus Steno, a brilliant student of anatomy, his fame is still associated with the eponym of the excretory duct of the parotid gland and of several other anatomic structures. He is one of the most famous truants of medicine, having at the height of his fruitful scientific career deserted anatomy to find salvation in the Catholic faith and to become titular Bishop of Titopolis. He returned to Copenhagen and remained there for a while as professor of anatomy, and propagated his new faith, but mental conflicts soon forced him to resign again. He died a short time later at the early age of thirty-eight.

Gabriele Fallopio³² (1523-1562), another famous anatomist, successor to Vesalius at the University of Padua, published his *Observationes anatomicae* in 1561. In this book he described in detail the ovaries as well as the uterine tubes, now known by his name, although he did not discover them. He had also observed the corpus luteum, which he described as "velvety vesicles filled with water or a watery fluid sometimes yellow, sometimes like a truly clear swelling." Both Fallopius and Stensen believed that the ovarian follicles were true ova. It was left to the former's pupil Volcherius Coiter³³ (1534-1590) to publicize this observation in 1573, crediting his teacher with it. Coiter himself believed that the ovaries corresponded to the seminal vesicles rather than to the testes and stored the female semen.

The "yellow body" of the ovaries, however, was not described fully or known by this name until Marcello Malpighi³⁴ (1628-1694) studied it carefully with a crude microscope and called it the "corpus luteum" in the appendix (*De ovo incubato*) to the first volume of his *Opera* published in London in 1686. He had found it in virgin as well as in pregnant animals and believed it to be the substance that gave rise to the ovarian follicles, then known as the "ova." De Buffon³⁵ (1708-1788), a Frenchman, however, regarded it as a transient gland that secreted the seminal fluid of the female. It was not until 1766 that Albrecht von Haller³⁶ demonstrated that the corpus luteum was formed by a thickening of the wall of the graafian follicle after its rupture. From this time on the corpus luteum and the follicles were studied in their true physiologic relation.

In 1668 there appeared a book entitled *The Male Generative Organs*, by Regnier de Graaf³⁷ (1641-1673), of Schoonhaven, Holland. In this book is the first account of the nature of the ovarian follicles, then called "ovula." There followed four years later a more detailed study in *De mulierum organis generatione inservientibus*.³⁸ The reasons for the original preliminary note and the subsequent detailed elucidation of the same subject can be found in one of those disputes over priority in which several investigators simultaneously made the identical discovery. There exists a letter of 1668 — unpublished until 1672 — to Werner Rolink (1599-1673) by J. C. van Horne³⁹ in which he described the discovery of the ovarian follicles, then known as ova, prior to de Graaf's first announcement. For details of this chapter in the history of anatomy the reader is referred to the essay of Corner.⁴⁰ De Graaf did not claim priority for his observation. In fact, he spoke of the celebrated van Horne's having made this discovery, but von Haller³⁶ in 1766 coined the eponym "Graafian" vesicle or follicle, because of the detailed study by de Graaf, who rightfully deserves this credit. De Graaf also gave a detailed account of the corpus luteum, describing it as a glandular substance that formed herniations on the "female testes," and foresaw that the ovary formed ova. Rosenmüller⁴¹ in 1802 described originally the epoöphoron, later known eponymically as the "organ of Rosenmüller" or parovarium. The actual human ovum was finally discovered in 1827 by von Baer⁴² after many failures by other investigators.

The general historical background, as well as the development of the nomenclature peculiar to endocrinology, has recently been compiled with special reference to the male hormone.⁴³ A few pertinent notes, however, may be added. The famous physiologist Hufeland⁴⁴ (1762-1836), while a professor at the University of Göttingen, made this interesting statement in 1797: "The organs of generation have the power of secreting the finest and most spiritual parts of our nourishment. But at the same time they are so organized that these perfected and ennobled juices can again return and be received into the blood." Whether this was merely an adaptation of de Bordeu's theory or an original thought is difficult to ascertain. In a fundamental paper King,⁴⁵ of Guy's Hospital, London, in 1836 described the structure and function of the thyroid colloid, and demonstrated its passage into the lymphatics and blood stream as "indirectly surmised by Morgagni." His concept of true endocrine function seems well substantiated in the following excerpt:

Yet we may one day be able to show that a particular material is slowly formed and partially kept in reserve, and that this principle is also supplementary, when poured into the descending cava, to important functions in the course of its circulation, [and] the influence which it exerts upon the circulating fluid may be more or less needful for the healthy subsidence of the entire animal.

In English medical literature the term "endocrine" was first used casually by Crookshank⁴⁶ in February, 1914. In the United States, Halsted,⁴⁷ in one of the Harvey Lectures of the same year, referred to the endocrine glands as "hormonopoeitic." Blair Bell⁴⁸ in 1917 criticized the noun and the adjective "endocrine" and proposed in their stead the words "hormopoeiosis" and "hormopoeitic," respectively, for the ductless glands, a suggestion probably derived from Halsted's lecture. Abderhalden⁴⁹ in 1924 had suggested the word "incretions" for the internal secretions to differentiate them from the "excretions" (waste products), a name originally proposed by Roux in 1919. None of these terms, however, found popular favor, and all soon lapsed into oblivion.

In contradistinction to the singular testicular hormone so far known, the female sex hormones consist of at least two distinct principles: the luteal and the follicular factors, referred to as the progestins and the estrogens. It may be stated that the concept of hormones peculiar to a specific sex, or specific in their action, is no longer valid. Both types of sex hormones occur in either sex in a quantitative relation, and their action depends on the quantitative level and physiologic pathology rather than on specificity. It is preferable, therefore, to speak merely of sex hormones with androgenic or with gynecogenic actions.

At a time when the anatomy of the ovaries and the action or function of their products became known, the general study of endocrine secretions reached the stage of experimental investigation. Yet it is interesting to observe that the hormonal activities of the female gonads were among the last to be suspected, and their principles among the last to be isolated.

Sir Percival Pott⁵⁰ (1713–1788) gave one of the earliest descriptions of the effects of castration of mature women, and the gynecologist Battey⁵¹ (1828–1895), of Rome, Georgia, was among the first to suspect an endocrine function—or rather dysfunction—of the ovaries. In August, 1872, the latter performed the first ovariectomy for physiologic reasons, an event that again led to an acrimonious dispute with English surgeons who claimed priority. Battey had excised the normal and healthy ovaries for the relief of functional disorders, an operation done first only one month earlier at Freiburg, by Hegar. The latter's patient failed to survive, so that Battey deserves the credit for arriving independently at this decision. The rationale of this operation has since been amply justified by the discovery of certain specialized cells in the ovary that have an endocrine function, and the imbalance of which may lead to functional disorders.

Regis⁵² in 1893 claimed that the psychoses of the surgical menopause could be cured by the injection of ovarian juices. His ideas may have been stimulated by the claims of Brown-Séquard⁵³ with testic-

ular extracts. Curatullo and Tarulli⁵⁴ in 1896 suggested an endocrine function of the entire ovary. Knauer⁵⁵ in the same year observed atrophy of the uterus after removal of the ovaries, but was able to prevent this involution by transplanting ovarian tissues into the castrated animals. Halban⁵⁶ in 1900 demonstrated that ovarian skin grafts brought about normal puberty in guinea pigs castrated in infancy. Adler⁵⁶ in 1912 achieved similar results with crude watery extracts of the ovary when desiccated tissues had failed.

It was at the turn of the last century that Prenant⁵⁷ and Born⁵⁸ independently suggested that the corpus luteum had an endocrine function essential for the maintenance of pregnancy. Clark⁵⁹ in 1900 differentiated between the "true" corpus luteum of pregnancy and the "false" one of menstruation, and Corner⁶ in 1927 finally proved that the corpus luteum is not essential for the occurrence of menstruation. Fraenkel,⁶¹ a pupil of Born, believed the yellow body to be the only source of hormone production in the ovary. Loeb⁶⁰ in 1907 demonstrated specifically that the corpus luteum hormone prepared the uterus for nidation of the fertilized ovum by producing certain progestational changes in the endometrium, irrespective of whether pregnancy follows. If pregnancy did not take place, its effects resulted in a desquamation of the uterine mucosa—that is, in menstruation. Finally, Fraenkel⁶¹ in 1910 proved the endocrine function of the corpus luteum.

Long before anything was known about the corpus-luteum hormone, physicians differentiated "desiccated whole ovary" and "desiccated corpus luteum" preparations. It was then not realized, however, that neither had any therapeutic effects, since the concentration of hormones in them was negligible. It is claimed that virtually tons of desiccated ovarian tissue would be necessary to produce even minor estrogenic effects, and that no effective amounts of corpus-luteum hormone could ever be administered by such "ovarian pills." Frank⁶² stated in 1931 that "such things as desiccated ovary, desiccated testes, thymus and anterior-pituitary extracts can be given by pound or bushel, and the only effect that I can notice is a disturbance of a delicate stomach."

The qualitative as well as the quantitative determination of the luteal hormone—or of any hormone—depends entirely on reliable methods of detection and assay. The ideal methods are those of chemical reactions, but these, as in so many other endocrine products, are not yet feasible. Recourse has therefore to be taken to biologic methods. For this purpose there are available two methods for the assay of the luteal principle. The first, discovered by Corner and Allen⁶³ in 1929, utilizes a sexually mature rabbit, since its ovaries always contain ripe follicles, and since its uterine mucosa is always in the proliferative stage. An injection of

luteal extracts or of pure hormone transforms this mucosa into a "prepregnant" or "pseudopregnant" state.

The second method was developed by Clauberg⁶⁴ in 1930, and consists of bringing the infantile uterine mucosa of an immature rabbit into the proliferative stage by preliminary injections of follicular hormone. This is usually achieved after eight daily injections of ten mouse units. The luteal hormone to be assayed is then injected until a pseudopregnant uterine mucosa develops. The smallest amount of luteal hormone that will produce this result is the unit of potency, or rabbit unit. The standard, or international, unit was determined at the International Conference for Biological Standardization in London in 1935.⁶⁵ It is the equivalent of 1 mg. of the crystalline corpus-luteum hormone (beta progesterone) preserved in London.

Practicing physicians waited anxiously for a pure corpus-luteum extract, since many uses and indications had been theoretically foreseen. Hannes⁶⁶ in 1919 attempted to prevent spontaneous abortion with crude extracts. The mechanism of premenstrual tension was postulated by Frank⁶² in 1931, and Novak and Reynolds⁶⁷ in 1932 defined the motility factors underlying functional dysmenorrhea. Engle and his co-workers⁶⁸ after a series of careful studies suggested the importance of the luteal principle in the functional uterine bleeding disorders.

Weichert⁶⁹ in 1928 demonstrated the action of the corpus luteum hormone by the observation of definite changes in the uterus of animals, as previously described by Loeb⁶⁰ in 1907. For his experiments he used crude corpus-luteum extracts and injected them into the test animals. His claims were soon confirmed by other investigators. Corner and Allen⁶³ in 1929 prepared the first crude extract of luteal hormone from the ovaries of swine. Allen and Wintersteiner⁷⁰ and Butenandt and his co-workers⁷¹ in 1934 succeeded in isolating a crystalline form of the hormone. They determined its structure as a di-keto-steroid, with the empirical formula $C_{21}H_{30}O_2$. The final achievement, however, was the synthetic production of this hormone in pure form by Butenandt's⁷² laboratory, and soon by others, who prepared it from the stigmaterol portion of soy beans. This synthesis made possible extensive clinical study and application, since the hormone was completely reliable and free from other related compounds and side effects.

It is interesting to note that the natural hormone occurs in an extremely small relative quantity, in a ratio variously estimated as 1:40,000 in the human corpus luteum and 1:750,000 in the human placenta. The pure principle is now also synthesized from pregnanediol,⁷³ a progestin and excretion product found in pregnancy urine. The clinical results obtained with the pure hormone have substantiated the theoretical predictions, but even today its

effects have not been explored in their entirety. Clinical results depend on a chemically pure hormone of exactly known potency and of complete reliability.

The early terminology of the corpus-luteum hormone was variegated and confusing, because of the numerous nonproprietary and proprietary names for the same substance. Corner and Allen⁶³ called it "progestin" on account of its progestational activity. Hisaw preferred the name "relaxin"⁷⁴ for one principle because of its ability to relax the sacral and pubic ligaments in pregnant rodents, and the name "corporin"⁷⁵ for a similar factor because of its origin in the corpus luteum. Clauberg⁶⁴ used the names "lutein" and "proluton" for similar reasons, and Slotta⁷⁶ coined the terms "luteo-steron C and D" because of the steroid nature of the compounds. Finally, to prevent further confusion the leading investigators from all countries met in 1935 and agreed to use henceforth only the term "progesterone,"⁷⁷ which proved acceptable to all and is now the nonproprietary designation for the luteal principle. It is, however, limited to the pure crystalline hormone, the term "progestin" being used to denote the whole group of progesterone-like, or impure, substances.

Chemically, progesterone, as isolated in 1934, is pregnenedion-3-1-20-ol, and has the empirical formula $C_{21}H_{30}O_2$. It exists in two isomeric forms in the solid state only, and either of these forms can be easily converted into the other. In solution both forms are chemically and physiologically identical. Progesterone is synthesized from the stigmaterol portion of soy beans and from the pregnanediol of pregnancy urine. The orally effective derivative pregneninolone was discovered by Inhoffen and Hohlweg⁷⁸ in 1938 by the addition of an ethinyl radical to the follicular or the androgenic principles.

Although the corpus-luteum principle was at first the only female hormone suspected and sought, the early investigators soon realized that there must be at least another factor — and source of hormones — in the ovary. Marshall⁷⁹ in 1905 suggested that either the interstitial or the follicular cells of the ovary also secreted a hormone that would produce estrus. Halban⁸⁰ in the same year found that this follicular factor stimulated growth of and produced changes in the breasts. Adler⁵⁶ in 1912 produced estrous changes by the injection of watery extracts of the ovaries into virgin animals. Iscovesco,⁸¹ and independently Fellner,⁸² and several others in the same year prepared certain lipid extracts of the ovary that produced hyperemia in the uterus of castrate and immature rodents.

The name "estrus" is the same as the Latin word for gadfly, and was used figuratively to indicate intense sexual frenzy or heat in animals. It designates the restricted period of mating activity of female mammals, but not that of the primates. Recent experiments with the ovarian hormones have em-

phasized another aspect of estrus — namely, the rapid growth of the accessory sex organs. This growth introduces the period of rut proper, and is brought about by the follicular hormone. The follicular hormone is therefore primarily a growth hormone, whereas the luteal hormone does not have this property.

The earliest test for the follicular factor was developed by Aschner⁶² in 1913. He had observed in castrated female rodents growth of breasts and nipples and hyperemia of the vagina and the uterus three to seven days after the injection of ovarian and placental extracts. When Stockard and Papanicolaou⁶³ in 1917 discovered a typical estrus cycle in the guinea pig the phases of which could be accurately determined by the presence of certain cornified epithelial cell changes in the vaginal smears with beginning rut, an important forward step was made. This phenomenon was utilized by Allen and Doisy⁶⁴ in 1923 to develop a method for studying qualitatively the actions of this hormone. They observed changes from the normal leukocytes of the vagina of castrated rodents to cornified epithelial cells and squamous scales two or three days after the injection of follicular extracts, changes that occurred normally only in estrous females. Simultaneously they announced for the first time the isolation of a comparatively pure crystalline substance obtained from the follicular fluid of cows and sows, 3 mg. of which induced estrus in a rat; this amount they called "1 rat unit."

Less popular tests were developed in 1925 by Frank,⁶⁵ who claimed that the delay in contractions of the uterine strip when suspended in Ringer's solution was in proportion to the concentration of preceding hormone saturation. Blotvogel⁶⁷ noted an increase of the chrome-staining cells of the pericervical lymph nodes of castrated animals after injection of active follicular substances.

With such growth-indicators as measures of qualitative and quantitative biologic changes, the other sources of estrogens could be found and assayed in animal organs as well as in plants, and even among minerals. The collective term "estrogenic principle" refers to any substance that induces the growth of the accessory sex organs.

Courrier⁶⁸ in 1924 studied the action of this hormone on the menstrual cycle, and because of its importance in producing the follicular phase called it "folliculin," a name still commonly used. A year later Laqueur⁶⁹ coined the term "menformon," now used as a proprietary name. Glimm and Wade⁷⁰ preferred the word "feminin" for this principle. In 1925, Loew⁷¹ demonstrated the occurrence of follicular substances in the urine and the blood of normal women and called it "thelykinin" to signify its feminine activity. Collip⁷² named it "emmenin" after obtaining it from the placenta. It is to the credit of Parkes and Bellerby⁷³ to have introduced the term "oestrin" in 1926, a name later modified to

"estrone," designating the nonproprietary form for the follicular hormone.

Estrone is a fat-soluble principle derived from sterols. It was extracted in 1927 by Doisy,⁶⁴ who named it "theelin." Butenandt⁷⁵ in 1929 independently isolated and crystallized it, with the empirical formula $C_{18}H_{22}O$, and called it "progynon," a term also retained as a proprietary designation. Marrian⁷⁶ in 1930 isolated the excretory form of this hormone, known then as "theolol." It soon became evident that this hormone existed in numerous chemical forms with varying degrees of physiologic action.

The basic structure of the follicular principle is estratriene $C_{18}H_{22}$, empirically identical with estrane, the basis of all sex hormones, female as well as male. Estrone, or 17-keto-3-hydroxy estratriene, was synthesized by Butenandt⁷⁷ in 1933 from palm nuts, but is not the true secretion of the follicular cells. The actual hormone is estradiol, which was obtained in pure form by Schwenk and Hildebrandt⁷⁸ in 1933 by the reduction of the keto-form to an alcohol, and what has the empirical formula $C_{18}H_{24}O$.

To eliminate the confusion of different names and different potencies, the Health Organization of the League of Nations⁷⁹ in session at London in 1931 designated as the international unit 0.1 gamma of the pure crystalline substance estrone, since the true principle estradiol was not yet isolated. This unit is about one third as active as the original Allen-Doisy rat unit, and is based entirely on gravimetric measures. It makes no reference to the estrous effects in castrated rodents. In order to prevent misinterpretation with later preparations a second international standard was adopted in 1935 for the less potent but longer-acting benzoylated derivatives,⁶⁵ as measured by the benzoic acid ester of alpha estradiol, the di-hydro-estratriene, but even then its estrogenic equivalent to the keto-hydroxy form estrone was not defined.

The bursting human follicle contains 2 or 3 cc. of follicular fluid with an estrogenic equivalent of 8 to 12 mouse units.²⁵ Zondek and Aschheim¹⁰⁰ in 1927 demonstrated that the hormone is most likely produced by the thecal and granulosa cells of the follicle, but Allen¹⁰¹ believes that all ovarian tissues may produce it, as well as the corpus luteum and the placenta. It is not peculiar to the female, for Haessler¹⁰² in 1934 found that the urine of stallions contains five hundred times higher titers of it than do those occurring in the ovaries of mature mares.

It is not within the scope of this essay to discuss the chemical and physiologic interrelations of the sex hormones or their clinical status, all of which command an enormous literature. Brief mention, however, should be made of the nonbiologic estrogens used clinically. There are at least forty known substances with estrogenic activity, and among these the only nonbiologic compound so far

used belongs to the stilbestrol group. Cook and Dodds¹⁰³ studied hydrocarbons intensively and found that many had estrogenic activities. Schwerdtfeger¹⁰⁴ in 1931 demonstrated that some sea animals and insects possess estrogenic substances, whereas Silberstein and his co-workers¹⁰⁵ found them in actively growing bacterial cultures. Finally, Dodds¹⁰⁶ in 1938 discovered the stilbene compounds, which were unusually active in minute doses, and called the basic substance 4, 4-dihydroxy-stilbene "stilbestrol." The most promising of its derivatives is now known by the nonproprietary name "diethylstilbestrol," or 4, 4-dihydroxy- α - β -diethylstilbene. Clinically it acts like the natural estrogens but has some unpleasant side effects. It is not a steroid and is easily and cheaply prepared from common chemical reagents.

* * *

Thus ends the story of one of the most fascinating chapters of medical history. Primitive man, limited by the faulty observations of inexperience, cannot be condemned for imitating Nature in eating indiscriminately certain excretory substances in the hope of saving his life. One must marvel at the way in which progressive minds at the risk of death as heretics tried to advance human welfare but failed because of deficient knowledge, jealously guarded by despotic authority. Yet the pendulum swung on through the depth of the dark centuries, to reach its climax in the speculative theories of a century of enlightenment. But even logic failed because it was based on erroneous premises. Finally the pendulum swung back through another century that witnessed the beginning of exact experimental science, and completed its course only a few years ago when the chemical nature of the hormones was discovered.

The speculative mind does not rest, but wonders at the ingenuity of the chemical laboratory of the human body, not yet duplicated by creative powers. Whither will it lead? The close relations of vitamins, hormones and carcinogens are known. Will the human mind finally conquer in spite of the obstacle still deemed unsurmountable? But guessing is futile — unless based on facts and proved by experiment.

So one can do no better than epitomize the past in chronological order and await the revelations of the future:

- 1550 B.C. The *Papyrus Ebers*, the oldest medical book known, mentions more than forty animal and human products as remedies.
- 1400 The *Ayurveda* by Susruta regards menstruation as a periodic cleansing of the body, and mentions several organotherapeutic remedies for sexual disorders.
- 460 Hippocrates of Cos describes 2 cases of menopausal hirsutism. Greek medical ethics recognizes the sanctity of motherhood. The Greeks know the testes but not the ovaries.
- 300 Herophilus of Alexandria discovers the "female testes" or ovaries and the *meati spermatici* or ovarian tubes.

- 70 A.D. Pliny the Elder mentions the remedial qualities of menstrual blood among more than two hundred and fifty medicines of animal or human origin, as compiled by four hundred and seventy-three authors.
- 1250 Albertus Magnus recommends powdered uteri of hares as a remedy for female sterility.
- 1300 Henri de Mondeville assails the supremacy of Galen.
- 1541 Jean Ursinus, a French physician-poet, was subsequently called by Dana "the Author of Opothecrasy and Endocrinology."
- 1548 Thomas Vicary states the rationale of organotherapy.
- 1555 Andreas Vesalius describes the "irregularities" of the "female testes."
- 1561 Gabriele Fallopio describes the ovarian tubes and the yellow body of the ovary.
- 1575 Guillaume Rondelet advocates dried placenta for uncomplicated expulsion of retained secundines.
- 1621 Fabricius ab Aquapendente describes the ovaries of hens.
- 1663 Johann Joachim Becher's *Parnassus medicinalis illustratus* mentions forty animal and twenty-five human substances as remedies.
- 1667 Niels Stensen uses the name "ovary" for "female testes."
- 1668 J. C. van Horne discovers the ovarian follicles, but Regnier de Graaf describes them in detail.
- 1691 François Mauriceau suggests that conception is independent of menstruation.
- 1686 Marcello Malpighi coins the name "corpus luteum."
- 1690 Heidentrijk Overkamp believes that the "ova" — that is, follicles — secrete a substance into the circulating blood.
- 1696 Nicholas Venette believe that this substance causes menstruation.
- 1756 Percival Pott describes the effects of removal of the healthy ovaries in a young woman.
- 1766 Albrecht von Haller coins the eponym "graafian follicle."
- 1776 G. L. D. de Buffon regards the corpus luteum as the gland that secretes the "female semen."
- 1802 J. C. Rosenmüller describes the epoöphoron since known by his name.
- 1827 C. E. von Baer discovers the human and mammalian ova.
- 1872 Robert Battey for the first time intentionally removes the ovaries for menstrual disorders, an operation since known by his name.
- 1896 Curatello and Tarulli suggest an endocrine function of the ovary.
- 1898 G. Born and independently A. Prenant suggest an endocrine function of the corpus luteum.
- 1905 F. H. A. Marshall mentions a follicular hormone.
- 1910 L. Fraenkel proves the endocrine function of the corpus luteum.
- 1913 B. Aschner devises the first biologic test for the follicular hormone.
- 1919 W. Hannes for the first time uses corpus luteum extracts to prevent spontaneous abortion.
- 1923 E. Allen and E. A. Doisy devise the best test for, and isolate, the follicular hormone.
- 1929 G. W. Corner and W. M. Allen discover a biologic test for, and prepare the first crude extracts of, corpus-luteum hormone.
- A. Butenandt and independently E. A. Doisy crystallize the follicular hormone estrone.
- 1933 A. Butenandt synthesizes the follicular hormone from palm-nut oil.
- E. Schwenk and F. Hildebrandt obtain the true follicular hormone estradiol by reduction of estrone.
- 1934 A. Butenandt and independently W. M. Allen and O. Wintersteiner crystallize the corpus-luteum hormone progesterone.
- A. Butenandt synthesizes progesterone from soy beans.

SWEAT AS A CULTURE MEDIUM FOR FUNGI*

THEODORE CORNBLEET, M.D.,† AND ESTHER MEYER, M.S.

CHICAGO

IT HAS been realized that sweat can support the growth of fungi and that its excessive secretion is often the determining factor in infection. It is common to observe the presence of hyperhidrosis with eczematoid ringworm of the hands and feet. One of

by clinical observations, depends on an unconcentrated medium. The same material after concentration by evaporation has antiseptic powers. Peck, Rosenfeld, Leifer and Bierman² have shown that thermal sweat may have fungistatic properties acid

TABLE 1. Description of Plate Cultures.

TYPE OF EXAMINATION	SWEAT AGAR	SABOURAUD'S MEDIUM
<i>Trichophyton purpureum</i>		
Macroscopic	The colony had the same character as when the mold was grown on Sabouraud's medium except that it was smaller and growth was not so luxuriant.	The colony produced was thick and white, with a central umbo, and had a velvety appearance. The back of the colony displayed a typical rose-purple color. A minimum of aerial growth was present.
Microscopic	Mounts prepared from a giant colony 1 month old showed many microconidia, a few fuseaux and a racquet mycelium.	Mounts prepared from colonies showed numerous microconidia and a racquet mycelium. A fairly large number of fuseaux were seen.
<i>Trichophyton gypsum</i>		
Macroscopic	The colony had the same character as when the mold was grown on Sabouraud's medium, but it was smaller and growth was not so luxuriant. Two concentric zones were clearly apparent.	The colony produced was white and fluffy and had a boss at the center. It showed many aerial mycelia.
Microscopic	Mounts prepared from a giant colony 1 month old showed microconidia, a branched, segmented mycelium and a few spirals. No fuseaux were seen.	The mycelium was septate. Numerous microconidia, a racquet mycelia and several blunt end fuseaux were seen.
<i>Microsporum gypsum</i>		
Macroscopic	The colony grew more rapidly than those of other species but was a scant filamentous growth and attained a greater diameter than did the other colonies.	The colony showed a white, felty growth with a large central umbo. Later it assumed a yellowish color.
Microscopic	Mounts prepared from a giant colony 1 month old showed a racquet mycelium, numerous microconidia and an occasional fuseau.	Mounts showed a racquet mycelium. Numerous microconidia and fuseaux were present.
<i>Hormodendrum</i> species		
Macroscopic	Growth was very slow. A flat rather smooth colony with a fringe of aerial mycelium around the edge developed.	The colony was dark olive-green with a grayish nap. It presented zones, but they are not apparent in the photograph.
Microscopic	Mounts prepared from a giant colony, 1 month old, showed yeastlike spores in groups along the side of a segmented mycelium and also at the tip.	Numerous dark-brownish, yeastlike spores appeared in groups along the mycelia and at the tips.

us (T.C.¹) has shown experimentally that such infection can be clinically induced by conditions that favor increased sweating of the feet.

The growth of fungi in sweat, as demonstrated in the experiments reported in the present paper and

*From the Department of Dermatology and the Department of Bacteriology, University of Illinois College of Medicine.

†Associate professor of dermatology, University of Illinois School of Medicine; attending dermatologist, Cook County and Mount Sinai hospitals.

in reaction (below pH 7.0), particularly when concentrated, and that these properties depend on its content of acetic, propionic, caproic, caprylic, lactic and ascorbic acids. They have also found topical applications of these acid ingredients of sweat to be valuable in the treatment of fungus infections.

Bergeim and Cornbleet³ believe that freshly secreted sweat may have a mild antiseptic action,

owing largely to its acid reaction, for which lactic acid is mainly responsible. Evaporation of such sweat on the surface of the skin or elsewhere tends to lower the pH and to increase the concentration of lactic acid so that the sweat becomes much more effective in this regard.

Tests on incubation of sweat show, however, that there is also a tendency for the sweat to become alkalized owing to formation of ammonia by bacteria from the urea present. On the other hand, ammonia is more volatile than lactic acid, so that on evaporation much of it is lost and much of the lactic

In the present experiments, sweat was obtained by encasing the subjects as far as their necks in a rubber bag while they were seated in a heat cabinet. Incandescent lamps furnished sufficient heat to obtain from 100 to 200 cc. of sweat in twenty to thirty minutes. Collected material was passed through a Berkefeld or Seitz filter, and control samples of filtered sweat were observed for sterility. Tubes of freshly filtered sweat were inoculated with the fungi. A solid medium was also prepared and used in Petri dishes in the usual manner. This medium was made by autoclaving a 4 per cent solution

FIGURE 1. One-Month-Old Cultures on Sweat Agar.

The cultures on the left are on Sabouraud's medium, and those on the right are sweat agar. A — *Trichophyton purpureum*; B — *Trichophyton gypsum*; C — *Microsporon gypsum*; D — *Hormodendrum species*.

acid is regained. The volatile fatty acids are largely if not entirely formed on the surface of the skin by bacterial action on the lactic acid. Above pH 5.3 lactic acid is so completely ionized that few undissociated molecules of acid — on which much of the antibacterial action of the acid must depend — are present. The chief protective value of this acid lies, therefore, below pH 5.3. The volatile acids are less dissociated, and hence more effective, in the pH range of 5.3 to 6.2. Their most important role thus appears to be the extension of some degree of acid protection into these higher pH levels, which under certain conditions exist also on the skin.

Sweat is therefore capable of having quite diverse actions toward fungi, depending largely on the degree of evaporation that takes place. This parallels events in a solution of sugar; the diluted material can be attacked by fungi, whereas the concentrated material cannot. The changes in acidity or alkalinity are of course also important in determining the action of sweat on the fungi.

of agar at 15 pounds' pressure for twenty minutes. Four cubic centimeters of autoclaved agar solution was added to 6 cc. of sterile sweat, which had previously been heated to 50° C., and the mixture was poured into a sterile Petri dish. The material solidified and appeared like other agar media. The tubes of sweat and Petri-dish preparations were inoculated with fungi — *Trichophyton purpureum*, *Trich. gypsum*, *Microsporon gypsum* and *Hormodendrum species* — obtained from patients with cutaneous infections.

Transfers from the first cultures prepared in sweat were made to sweat-agar Petri dishes in order to obtain giant colonies. It was necessary to make transfers approximately three times to fresh dishes during the course of the work, because contaminants had entered the original dishes during the long incubation period and the latter were therefore unsuitable for the taking of photographs. Colony growth was the same each time, and no pleomorphism was observed. One-month-old cultures were used in all

cases for the photographs (Fig. 1) and descriptions (Table 1).

For the tube cultures, transfers were made of each fungus to tubes of sweat that had been previously filtered through a Seitz filter and allowed to incubate at room temperature. Growth was slow in starting but grew well after the initial lag. Consid-

these tubes after an incubation period of one month. The cultural characteristics are given in Table 2.

DISCUSSION

The superficial fungus infections of the skin take place within or on the keratin layer. It is well known

FIGURE 2. One-Month-Old Cultures in Sweat.

Starting at the left, the cultures are, respectively, as follows: *Hormodendrum species*, *Microsporon gypseum*; *Trichophyton purpureum*; and *Trich gypseum*.

erable evaporation had taken place after one month, so subcultures were made to a second series of sweat

TABLE 2 Description of Tube Cultures.

<i>Trichophyton purpureum</i>	The fungus grew slowly and was white and velvety on the surface of the liquid. There was also a small amount of growth at the bottom of the tube.
<i>Trichophyton gypseum</i>	The fungus grew slowly and was white and velvety on the surface of the liquid. No growth took place at the bottom of the tube.
<i>Microsporum gypseum</i>	The fungus grew rapidly, producing a white, felty mycelial growth about 1 cm. in height on the surface. There was a small amount of growth at the bottom of the tube.
<i>Hormodendrum species</i>	The fungus grew very slowly, and there was more growth at the bottom of the tube than at the top. Mycelial growth was below the surface, while the surface growth was smooth and leathery.

tubes. These subcultures grew more rapidly than the initial ones did. The photograph (Fig. 2) shows

that keratin and related products serve well for the growth of fungi; thus, they are found growing on feathers and leather. Keratin is rich in sulfur-containing amino acids, and this raises the question of the relation of this element to fungus growth. If the sulfur is a requirement for the thriving of fungi, it must be present in such a form as not to lead to the production of sulfides. Cornbleet and Bergeim⁴ have found that fungi are extremely sensitive to hydrogen sulfide and are killed or prevented from growing by extremely small concentrations.

Fungi also need moisture for growth and this is furnished by the sweat, but sweat alone can support

the growth of fungi, as shown in the above observations. Just what factor in sweat is the chief support of growth cannot be said. There are lactic acid and also volatile fatty acids. Some observers⁵ have found sugar in sweat, although this conclusion may have resulted from the presence of reducing substances. There are sulfur-containing substances, although cultures of the hyphomycetes in sweat that were tested did not contain hydrogen sulfide. The same mediums, however, used for growing a number of varieties of bacteria did contain it.

So far as can be seen at the present, this study cannot be put to practical use. It may be that sweat mediums will be found to be useful for the differentiation of certain species that is difficult by other means. Such capacity was not shown in this study, but only a few varieties of fungi were used. No pleomorphism was shown for any of the cultures in three months of observation, so that they are fairly stable on these mediums.

SUMMARY

A description is given of several fungi that were grown on sweat and a medium made of sweat and agar.

The role of sweat as an antiseptic and as a nutritive source is briefly reviewed.

Certain aspects of the natural growth of the hyphomycetes on the skin are considered, and the relation of some constituents in sweat to this growth are discussed.

MEDICAL PROGRESS

GYNECOLOGY: CARCINOMA OF THE CERVIX (Concluded)

JOE V. MEIGS, M.D.*

BOSTON

THE series of cases reported in Table I have been classified by the League of Nations method and are from clinics large enough to have a sufficient number of cases to be significant. These results have been accepted by the Health Organization of the League of Nations and have been analyzed by Heyman.²⁰ They show how little variation there is from class to class and from total to total. There is no single way to treat cervical cancer, and Miller's³ remarks, quoted at the beginning of this paper, cannot be better proved than by these results. It will be seen that the widest variation is in the Class III cases, and here is the greatest chance for errors in diagnosis, for some of these patients may have had only inflammatory nodes or masses and not cancerous masses, and thus an advanced case may have been reported as cured. If one could eliminate the Class III cases, there would be a close consistency of results. This discrepancy is probably due to incorrect evaluation, possibly to a better method of treatment.

In the surgical cases, Bonney's²⁷ curability of 40 per cent of those operated on is the only figure of consequence available.

PROGNOSIS

A prognosis cannot be made from a study of microscopic slides alone. Since slowly growing tumors may be radioresistant and since rapidly growing

tumors may respond but metastasize rapidly, it is the cases with a moderate grade of malignancy that do best. Early cases do better than late ones. Cases with distant metastases have a high mortality. If a patient has symptoms for more than six months, she is usually in the inoperative and incurable group. Goldscheider⁴ believes that pyrexia in the course of x-ray treatment is an unfavorable sign. In order to evaluate the results of a method of treatment in a shorter time than five years, Meigs and Jaffe²⁵ were able to show that if 10 per cent is deducted from the three-year survivals for the fourth year and 5 per cent for the fifth year, the five-year end results can be estimated. Warren, Meigs, Severance and Jaffe²⁶ showed in a study of biopsy material taken before, during and after combined radium and x-ray treatment that if a tumor does not respond to treatment, as shown by destruction of cells, abnormal mitoses and an increase in connective tissue, the outlook is usually fatal. Nilsson²⁷ believes that the prognosis in cases of adenocarcinoma of the cervix is not so favorable as that in squamous-cell cancer, but his findings are not borne out by other authors.

COMPLICATIONS

The complications of cervical cancer that are due to its growth alone are destruction of the bladder and rectum and blockage of the ureters. Later in the progress of the disease hemorrhage and distant metastases to vital organs occur.

*Assistant professor of gynecology, Harvard Medical School; chief, Gynecological Service (Vincent Memorial Hospital), Massachusetts General Hospital.

Vesicovaginal fistula and rectovaginal fistula in untreated cervical cancer are not rare. Smith³⁸ believes that fistulas are twice as frequent in untreated cases as in treated ones and that they are evidence of advanced disease. He estimates the incidence of rectovaginal fistula as in 75 cases, that of vesicovaginal fistula as 1 in 92 cases and a combination of both as 1 in 129 cases. Death in untreated cases is often due to ureteral block and uremia. If it is desired to stop severe hemorrhage from a cervical cancer because of the favorable aspect of the

cases with serious bowel injury, comprising about 2 per cent of the total number of cases treated. This injury is probably a small price to pay in the treatment of this disease, but it may indicate that too heavy treatment with the x-ray machine is being used. It is also true, however, that the same injury may occur with radium alone. Wigby⁴⁴ in 1943 reported some reaction in the sigmoid in 24 out of 100 patients. The injuries included hyperemia and edema, ulceration and bleeding, edema and pain, and obstruction. Pyometrium, peritonitis, pelvic

growth, Leventhal, Lash and Grossman³⁹ advise extraperitoneal ligation of the hypogastric arteries. This should not be difficult to accomplish.

Ureteral block is not uncommon. Graves, Kickham and Nathanson⁴⁰ reported from the Pondville Hospital that 70 per cent of their cases had obstruction of the ureters and that complete urologic investigation was necessary. Also reporting from this hospital, Jaffe, Meigs, Graves and Kickham⁴¹ state their belief that management of the obstructed ureters by means of nephrostomy frequently saves the kidneys. Treatment is omitted while the temperature is high and is resumed after nephrostomy has allowed it to return to normal. After the edema has subsided and cancer has been destroyed, the ureter may function normally. It was due to the above investigations at the Pondville Hospital that the Urologic Clinic dealing with the urologic complications of cervical cancer was established there.

Bowel injury following radiation treatment is not infrequent. Jones⁴² and later Aldridge⁴³ have reported a series of serious injuries to the bowel by x-ray treatment. Jones describes severe injuries in 7 of 520 treated cases. In 5 of these the large intestine was affected, and in 2 the small intestine. Aldridge thinks that in many cases sufficient radiation to cure the patient cannot be given without damage to the intestinal tract. A great many of the manifestations of bowel injury, such as diarrhea, tenesmus and bleeding, are simple, but at a subsequent time—from months to years later—cicatization may occur, with damage to the small or large intestine, necessitating colostomy to allow the bowel to heal or hemorrhage to cease, or even resection of the small or large bowel for obstruction. From the clinics at the Massachusetts General Hospital and Pondville Hospital I have collected 47

inflammation and so forth may follow combined radium and x-ray treatment. Philipp⁴⁵ and later Miller and Folsome⁴⁶ have reported fractures of the neck of the femur following radiation treatment for cervical cancer. This has led to the elimination of the lateral portal for treatment in some clinics. Martin⁴⁷ recognizes the danger of radiation and has tried to prevent untoward reactions. He has substituted multiple sources of radium of moderate intensity and frequently shifts containers of high intensity. He increases the distance for vaginal applicators by means of vaginal packs. He changes the packs frequently, uses no radon implants, avoids the ureters and employs intensive x-ray treatment only in advanced cases. He has elevated the lateral portals of treatment and gives his therapy in one careful series. He also allows a long interval between x-ray treatment and radium treatment. With all these measures I cannot agree, but the steps Martin is taking show that he has encountered difficulties, as have all clinics, and is searching for a way out of them.

CAUSES OF DEATH

The cause of death in most patients with cancer of the cervix is interference with the urinary tract, blocking of the ureters and uremia. Hemorrhage is a not infrequent complication, and large fatal ones due to erosion of a large artery are not uncommon. Many patients with cancer of all kinds die of persistent depletion due to loss of weight, lack of appetite, obstruction of the bowels, pyrexia and so forth.

PREVENTION

Improvement in the methods of reconstruction of cervical injuries comprises one means for the prevention of cervical cancer. The use of office cautery

and repair or operation on the cervix will surely aid in avoiding cancer, but even perfect repair or perfect reconstruction will not prevent it if all the cancer-producing factors are present. It is not known how long it takes malignant disease to develop, how it starts or from what sort of tissue it arises.

The best method of prevention is excision, and the only type of excision that completely removes the cervix is total hysterectomy. This cannot always be advocated, but with the decreasing mortality from this operation it is probable that the number of unsuspected cervical cancers found in the laboratory will approximate the number of deaths from the operation. No one can advocate removal of the uterus and cervix in every married woman over the age of thirty, but one can properly advise, if for any reason abdominal operation is necessary, not that repair, cauterization and amputation be done but that the uterus and cervix be completely removed. This can be called radical advice, but to one who has seen cervical cancer develop in 2 cases after cauterization and supravaginal hysterectomy it does not seem at all radical. If total hysterectomy cannot be done with so low a mortality as supravaginal hysterectomy, each case should be sent to someone who can do it. A discussion of cancer of the cervical stump will be given later.

Schmitz,⁴¹ Macfarlane et al.⁴² and Phaneuf and Belson⁴³ advise observation of the cervix. Schmitz says that this should be made once a year; Macfarlane, who examined 1000 women, says twice a year; and Phaneuf and Belson biopsied 100 consecutive patients. Macfarlane et al. found 4 cases, and Phaneuf and Belson also found 4 cases. The early recognition of cancer is so difficult that in any suspicious case it is much safer to remove the cervix than to leave it, and total hysterectomy is the best method of prevention.

Von Graff⁴⁴ found that cancer of the body of the uterus was nine times as frequent and cancer of the cervix four times as frequent in patients with fibroids as in those with a normal uterus, so that in such cases total hysterectomy is the procedure of choice.

PREMALIGNANT LESIONS AND VERY EARLY CANCER

The question of premalignant lesions is a much disputed one, and it is not yet clear what part epidermalization and squamous-cell metaplasia play in the development of cancer of the cervix. Knight⁴⁵ in reporting 17 cases of superficial epithelioma states that cancer occurs not infrequently in tissue that has undergone squamous-cell metaplasia. He believes that the latter may be important and may be the early phase of intraepithelial cancer. Mezer⁴⁶ in a careful study of 1636 cases of polyp found 5 with cancer; in all of them the polyps were associated with squamous-cell metaplasia. It is doubtful that the time has yet come when total hysterectomy can be advocated by the pathologist because of the

finding of epidermalization and squamous-cell metaplasia, for such conditions have been seen in patients who have been followed for many years after the diagnosis was made. Nevertheless, it is also obvious that such a condition cannot be overlooked and that a careful follow-up for years is essential.

The question of cancer in situ, or intraepithelial or preinvasive cancer, is also not yet decided, but it is recognized by such an authority as Meyer⁴⁷ as being carcinoma. The experience of many is that if cancer in situ is present in a biopsy specimen, there may be invasive cancer in some other area in the cervix. Investigations at the Pondville Hospital indicate that the diagnosis of preinvasive cancer indicates that more biopsies should be made of various areas in the cervix. Thus, all but one of the preinvasive lesions were found to be true invasive cancer. Perhaps all that needs to be done for patients with preinvasive cancer is a total hysterectomy, but inasmuch as cure depends on radical removal, the Wertheim operation is not out of place. Schiller⁴⁸ and also Stevenson and Scipiadès⁴⁹ believe that early cancer grows slowly. The latter followed a woman with preinvasive cancer for eight years and one month, and the cancer finally became invasive. Another patient was followed for three years, and after death, serial sections of the cervix showed invasive cancer. It is probable that cancer in situ or preinvasive cancer cannot be considered as Bowen's disease, for that lesion remains intraepithelial. Knight⁴⁵ states that it is not much like Bowen's disease. The use of radium in very early preinvasive cancer may be sufficient. Amputation of the cervix is not sufficient, for it does not remove all the endocervical epithelium. Total hysterectomy is therefore best; yet, as most cases show invasive cancer, perhaps the more radical Wertheim method should be advised.

To sum up, changes in the type of cervical epithelium are probably due to inflammation, yet it is not at all certain that such changes are not part of the picture of malignant change. Cancer in situ must be regarded in the light of our experience as early cancer, and the proper treatment is either full radium or x-ray treatment or total hysterectomy, or, even better, the Wertheim operation.

CANCER OF CERVIX AFTER SUPRAVAGINAL HYSTERECTOMY

This problem of cancer of the cervix after supravaginal hysterectomy is a real one, and anyone seeing large numbers of cervical cancers is struck by the great number of such cases. These cases are of two kinds, those in which the operation is done at the time the cervical cancer is present, and those in which the cancer develops some years later. I have had under my supervision at one time 3 patients in whom supravaginal hysterectomy had been done when they had obvious cervical cancer. This is inexcusable and is due to lack of inspection and ex-

amination of the cervix at the time of operation. It is probable that these patients were bleeding and had fibroids, and that the abdominal operation was done and the uterus removed without preliminary inspection of the cervix in the lithotomy position. In other cases the cancer develops within three to six months postoperatively and was certainly present at the time of the operation, but was not recognized because it was so early or was present in the endocervix. This type of mistake is more excusable than the former, but in either, if the patient had had a total hysterectomy instead of a supravaginal hysterectomy, the results might have been better. In still other patients the tumor occurs from two to twenty-five years after the operation. It is pathetic to see such patients, for they believe that when they were operated on the uterus was removed. Surgeons leave the cervix behind because of the danger of morbidity, because of the possibility of interfering with sex activity and because they fear the more difficult operation.

With the advances in the knowledge of the operation and better preparation of the patient for it, there is no excuse for not removing the cervix. In certain cases—in bad-risk patients and in obviously difficult operations—the cervix may be left, but this should be the great exception and not the rule. In 1934, Gellhorn and Spain⁵⁷ stated that the danger of total hysterectomy is far less than that of cancer of the cervical stump. Von Graff,⁵¹ who reported 581 cases of this disease, believes that in 137 cases (23.5 per cent) it was present at the time of the operation and that the remaining cases would have been cured by total hysterectomy. He condemns "coning out" the cervix as not being sufficient treatment, since it leaves the squamous-cell epithelium on the outside of the cervix. Behney⁵⁸ believes that the chance of curing cancer of the cervical stump with radium is no less than that in corresponding classes of cervical cancer with the uterus left intact. Ward⁵⁹ agrees with his conclusions. It is the experience of our clinics that the treatment is not so efficacious because the canal of the cervix cannot be used as the source of the central radium applicator. The danger of fistulas, as all agree, is greater because the protection of the uterus is absent. It has been the custom in some clinics to do a vaginal cervicectomy in early cases of cancer of the cervical stump, and good results have been obtained, but if surgery is to be done in early cases, whether in the cervical stump or in the untouched uterus, the Wertheim operation with its radical removal of nodes and vaginal tissue is the procedure of choice. The percentage of cancer of the cervical stump among cervical cancers is 3 to 4 per cent in all clinics, — not a very great number, — but at the Pondville Hospital there have been over 100 cases. The sad thing about these cases is that if the total operation had been done, no patient would have developed cancer.

RELIEF OF PAIN

The treatment of pain in cervical cancer is usually limited to patients with advanced disease who are not likely to be cured. Cleanliness, frequent douching, changing of dressings and bed rest help a great deal. The use of acetylsalicylic acid (aspirin), codeine and narcotics is familiar to all, yet there are patients whose pain cannot be controlled by ordinary measures.

Sometimes x-ray treatment distributed over the area of pressure and invasion by the tumor is of value. There are, however, many advocates of the use of intrathecal injections of absolute alcohol (Todd⁶⁰). This method is undoubtedly satisfactory in some cases, but in the great majority if sufficient alcohol is injected to stop pain, some sort of interference with the function of the bladder and rectal sphincter takes place and weakness of the legs occurs. The length of the relief from pain varies from a few hours to a few months. Certainly in hopeless cases this method can be tried, but no guarantee can be made that the patient will obtain a satisfactory result.

The use of sympathectomy for control of pain has been advocated by Todd, who does a presacral sympathectomy. Others, among them Waterman,⁶¹ have reported success with this type of operation. Relief can be obtained from pain in the midline, but in most cases it is not satisfactory. Chordotomy has distinct possibilities, and unilateral or bilateral section of the arteriolateral columns is not an extremely formidable operation and may be carried out under local anesthesia. These patients lose the sense of pain and temperature but not that of touch; they are not paralyzed. In patients with severe pain and with not too advanced cancer who appear to be going to live for months this operation offers a great deal, but for patients who are near demise alcohol injections are just as efficacious. The trouble with the operation is that it is usually done when the patient is in extremis and is shortly followed by death. Its use in earlier cases gives results that are more satisfactory. The danger of interfering with the bladder and rectal sphincter is a real one, but the relief of pain in hopeless cases is well worth the risk.

CANCER OF CERVIX IN NULLIPARAS

Nulliparas constitute a fairly high percentage — from 5 to 12 per cent — of patients with cancer of the cervix. It is often impossible to state whether a married nullipara has ever miscarried, and in the unmarried patient the question of whether a pregnancy has occurred is often a difficult one to ask. Since cancer of the cervix does occur in nulliparas, pregnancy or labor is not essential for the development of the disease. Nulliparas may have had endocervicitis before the development of cancer and may have had an exposed endocervix, with irritation. The knowledge that cancer is not too

infrequent in nulliparas is important, so that a surgeon will not content himself with doing a supravaginal operation merely because the patient has had no children. Careful inspection of the cervix must be done before a supravaginal operation, and its removal with the uterus is far better. Inasmuch as many nulliparas have fibroids, and since cancer of the cervix is more frequent in patients with fibroids than in those with a normal uterus, removal of the cervix in such cases is essential.

CANCER OF CERVIX IN PREGNANCY

Keller⁶² reports 3 cases of cancer of the cervix among 4000 pregnant women. The patients had no symptoms, the tumor being discovered at biopsy. Danforth⁶³ found the frequency during pregnancy to be 0.03 per cent. There is no agreement whether pregnancy causes an abnormal rate of growth of the cancer. Miller⁶⁴ believes that it does, but quotes Wagner, Weibel, Meyer, Schweizer and others who believe that it has a retarding influence. Smith⁶⁵ states that pregnancy is detrimental to patients with unarrested malignant tumors. He thinks that the tumor growth may be retarded by the pregnancy but that it is accelerated afterward.

The mode of treatment of cancer of the cervix in the pregnant woman must be decided according to the size of the conceptus. Keller⁶⁶ agrees with Brouha and Gosselin⁶⁶ that in the first half of pregnancy a hysterectomy should be done in operable cases and that radium should be given in inoperable ones. They advise against x ray treatment in the first half because of its deleterious effect on the fetus. They believe that in the second half radium is ideal and has but little effect on the fetus. They allow the pregnancy to go to term and do a cesarean section. Danforth⁶⁷ believes that labor may be dangerous and is occasionally impossible, and advises x ray and radium at once when the pregnancy is far enough advanced to allow viability. He advises termination of the pregnancy if full treatment is given, because of the danger to the child. Brouha and Gosselin⁶⁸ analyzed 39 cases, including 2 of their own. In 10 cases radium was given in the first half of pregnancy, and in 7 an interruption of the pregnancy occurred in one to five and a half months. Three patients went to term and gave birth to normal children. Twenty-nine had radium, in the second half of pregnancy, and in this group there were 6 miscarriages and 2 fetal abnormalities. Eight of the mothers treated in the first half of pregnancy died. Of those treated in the second half of pregnancy, 19 were traced and 9 were living and well. These writers conclude that since irradiation in the first half of pregnancy is dangerous to both mother and child, a hysterectomy should be done. In the second half radium should be given, and if a miscarriage occurs a hysterectomy should be done at once. Hurdon⁶⁷ gives the incidence of cancer of the cervix in pregnancy as 0.5 to 2.0 per cent. In her

clinic the percentage was 0.6 per cent. She cites Pankow as collecting 50 cases of carcinoma during pregnancy that he had operated on with a five-year survival rate of 42 per cent. Hurdon believes that the uterus should be emptied because spontaneous abortion occurs two to four weeks after radiation without complications. She warns of the possibility of injury to the germ plasma of the child whose mother's cervical cancer has been irradiated. She states that there may be danger of transmitting germ plasma defects. On the other hand, there are children who have been delivered following irradiation of their mothers who have arrived at school age without any apparent physical defect. Hurdon's summary of the treatment of cancer of the uterus complicating pregnancy is excellent, and is presented below.

If the cancer is discovered during pregnancy

If the cancer is operable and the child not viable

Radical excision (Wertheim) of the unopened uterus

The prognosis for the mother is comparatively good.

Radium therapy. If not followed by abortion, evacuate by abdominal hysterotomy or the child may go to viability and be delivered by cesarean section. The prognosis for the mother is favorable. Abortion usually follows and abnormalities are frequent among the children that survive.

If the cancer is operable and the child viable

Cesarean section followed by Wertheim's operation. The prognosis for the mother is unfavorable, there is a good chance of survival for the child.

Radium therapy preceded or followed by Cesarean section (according to the period of gestation). The prognosis for both mother and child is comparatively favorable.

If the cancer is inoperable and the child not viable

Radium therapy followed by delivery by abdominal hysterotomy (in accordance with religious principles, pregnancy may be allowed to continue, with delivery by cesarean section at or near term).

If the cancer is inoperable, and the child viable

Radium therapy preceded or followed by cesarean section (according to the period of gestation).

If the cancer is discovered at the time of labor, and the baby is alive

If the cancer is operable

If the presenting part is still in the uterus
cesarean section followed by Wertheim's operation

If the presenting part is through the cervix

Labor followed by radiation treatment (as soon as in-volution permits). Treatment may be begun by x ray therapy a few days after delivery, and in tracheotomy radium as soon as practicable. The beginning of treatment should not be delayed beyond the ninth or tenth day.

If the cancer is inoperable

If the presenting part is in the uterus
Cesarean section followed by radiation therapy

If the presenting part is through the cervix

Labor followed by radiation therapy (as soon as in-volution permits).

The following criticism of Hurdon's advice should be made. If the cancer is operable and the child viable, it is perhaps better to do a cesarean section and then give radium to the cervix, and six weeks later to operate by the Wertheim method. The huge veins, the large lymphatics, the soft tis-

sues and the obvious danger of the infected cervix suggest treatment with radium, sterilization of the cervix by radiation and later operation. In cancer discovered at the time of labor, radical surgery should not be done for cervical cancer at the same time as cesarean section, for the reasons given above. There have been 3 such cases in our clinics. The first patient, who had been pregnant for six months, was given radium. A cesarean section was done at eight months; then x-ray therapy was given and radium treatment was repeated. The patient died of extensive miliary metastases one year after treatment. The second patient was given radium in the sixth month of pregnancy and had a cesarean section in the eighth month. The baby died of hemorrhagic disease of the newborn, and the mother was given further radiation and has been alive and well for over five years. The third patient was six-months pregnant, with an early growth. She was given radium in the cervix, a cesarean section was performed six weeks later, and three months after that a Wertheim hysterectomy was performed. The patient is alive but has a ureteral fistula, which means later nephrectomy. She had no metastases in the lymph nodes and should do well. A transverse cervical cesarean section had been done, and this interfered with the dissection about the cervix at time of the Wertheim operation. In another such case, it would seem wiser to do the classic operation rather than the cervical.

Hurdon discusses 15 cases of pregnancy subsequent to involvement of the cervix with cancer. Spontaneous delivery occurred in 8 cases, and 1 patient was delivered by cesarean section. Abortions were induced in 2 cases, and were spontaneous in 3. One patient had three abortions before a normal child was born. One child was delivered by morcellation. All the living children were said to be healthy, both physically and mentally. There are no records of a second generation.

SUMMARY

The treatment of cancer of the cervix by radiation is at a standstill. Radium alone and combined with x-ray has given excellent results. It is now time to concentrate on early diagnosis by means of the vaginal smear, the colposcope and the Schiller test. The addition of surgical removal of the lymph nodes and the radical Wertheim's operation in favorable cases may produce better results.

Cervical cancer can be prevented only by total removal of the cervix by total hysterectomy when it is irritated, lacerated or suspicious.

Various problems of cervical cancer are discussed.

CASE 30201

PRESENTATION OF CASE

A twelve-year-old mongolian girl entered the hospital because of vomiting and fever.

The patient was normally delivered at full term. The parents were normal. Development was slow, and she presented such a feeding problem that, at

with vomiting and diarrhea for several days. These cleared with a special diet. She remained in essentially good health until 4:00 a.m. on the day before admission, when she suddenly started to vomit. The vomiting was "explosive," and continued during the day; the vomitus consisted of "white curdy and butyry masses, stool-like, with no bile." There was slight watery diarrhea, which stopped by mid-afternoon of that day. Tenderness was elicited in the "lower intestine." The abdomen became distended. She developed fever and the white-cell count was 29,200, with 82 per cent neutrophils. The red-cell count was 3,840,000. She continued to vomit occasionally during the following night but was slightly more comfortable on the morning of admission. Distention of the abdomen and tenderness became marked, especially on the right. She was transferred to this hospital.

Physical examination showed a slightly cyanotic, underdeveloped, typical mongolian girl. The heart and lungs were negative. The abdomen was distended and tympanitic. Peristalsis seemed to be

FIGURE 1. Photomicrograph of Kidney.

three, she was a seriously malnourished child. Dentition started at eight months, walking at nineteen months and talking at three years. She had measles and whooping cough as a child. At the age of six a diagnosis of mongolism was made, and about three years later she was placed in an institution. During the first year there she had recurrent ulcerations of the mouth, from which smears occasionally showed Vincent's organism. In the following two winters she had occasional episodes of "stomach upset,"

*On leave of absence.

depressed, and infrequent high-pitched sounds were heard. The liver was two fingerbreadths below the costal margin. The spleen was not enlarged. There was spasm on the left side of the abdomen. It was difficult to judge tenderness, but on one occasion the patient shrieked bitterly on deep palpation in the right lower quadrant. There were no masses. Rectal examination was negative.

The blood pressure was 155 systolic, 120 diastolic. The temperature was 101°F., the pulse 160, and the respirations 40.

Examination of the blood showed a white-cell count of 28,000. The urine contained occasional white cells, but was otherwise negative.

During the examination she became completely unresponsive and began to show peculiar gyrating motions of the arms. She became cyanotic, with an unusual mottled distribution. Rapid epileptiform convulsions began and persisted in varying degrees of severity for one hour. She was given 1 gm. of sodium phenobarbital and 10 cc. of paraldehyde. A lumbar puncture at the end of this time showed clear fluid, which contained 6 lymphocytes per cubic millimeter; the Pandy test was negative. Following this, she became irritable and irrational, thrashed about the bed and required restraint; 12 cc. of paraldehyde was given. About one hour later she suddenly threw herself on her face and vomited a slight amount of brownish material. The pulse was

I thought of the possibility of malrotation, with twisting and intestinal obstruction as a result. Most cases of malrotation, however, are seen relatively early in life, and it would be unlikely for a patient to reach the age of twelve and suddenly to develop such a condition. The only one that I can think of is a *volvulus of the cecum* and ascending colon, which I do not see how I can rule out.

Are there any x-ray films of the abdomen?

Dr. BENJAMIN CASTLEMAN: No.

Dr. LINTON: Another condition that should be considered is reduplication of the intestinal tract, which gives signs of intestinal obstruction; again, I cannot rule this in or out. One also has to consider a Meckel's diverticulum, which might produce intestinal obstruction owing to strangulation of the bowel around a fibrous band extending from the end of the diverticulum to the abdominal wall. Intus-

FIGURE 2. Photomicrograph of Heart.

irregular, with a rate of 30. Three minutes later, three hours after entry, no heart beat could be heard.

DIFFERENTIAL DIAGNOSIS

Dr. ROBERT R. LINTON: We have here a typically mongoloid individual who entered the hospital because of an abdominal condition. Diagnosis is most difficult, since we have little if any evidence except the clinical examination and a very short history. In view of the high white-cell count one should consider an inflammatory condition, perhaps something that was obstructing the blood supply of the bowel, with secondary infection resulting from it. I believe, but I do not know, that congenital anomalies are not infrequently found in this condition. So one has to consider some of the congenital conditions that might produce vomiting, abdominal pain and distention and a high white-cell count. The temperature was 101°F. on one occasion.

susception is also something that one should consider, but I think that it can be ruled out, since 75 per cent of the cases of intussusception appear before the age of one. Another condition is an intra-abdominal herniation, as well as other congenital conditions that arise in the abdominal cavity.

I also thought of a peptic ulcer. Peptic ulcers with perforation do occur in children, but in view of the essentially negative past history I do not see how I can make a diagnosis of peptic ulcer.

There is another condition that I cannot rule out — appendicitis. The only thing against appendicitis is the sudden onset with an explosive type of vomiting, which is a peculiar way for appendicitis to manifest itself.

After running through the various possibilities I cannot make a definite diagnosis. I believe the likeliest was a *volvulus* of some portion of the intestine, interference of the blood supply, intestinal obstruction and peritonitis. The sudden death I

depressed, and infrequent high-pitched sounds were heard. The liver was two fingerbreadths below the costal margin. The spleen was not enlarged. There was spasm on the left side of the abdomen. It was difficult to judge tenderness, but on one occasion the patient shrieked bitterly on deep palpation in the right lower quadrant. There were no masses. Rectal examination was negative.

The blood pressure was 155 systolic, 120 diastolic. The temperature was 101°F., the pulse 160, and the respirations 40.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: Autopsy showed about a liter of turbid, hemorrhagic fluid in the abdominal cavity. The small intestine appeared red and gangrenous, and at the time of autopsy we thought that it had twisted and a diagnosis of volvulus of the small bowel was made. Microscopic sections, however, showed something extremely interesting, which perhaps accounted for the gangrene of the bowel.

In sections of the kidneys practically all the blood vessels, especially the medium-sized arteries, were diseased (Fig. 1). Many showed marked intimal proliferation, with practically no lumen; others had

tically complete destruction of the wall in some vessels (Fig. 4).

We have, then, a classic example of polyarteritis or periarteritis nodosa in a child of twelve, the youngest we have seen here. Involvement of the mesenteric vessels was the cause of the gangrene of the bowel. Lesions were found in practically every organ, including the brain, which may account for the convulsions.

DR. BUTLER: How sure is Dr. Benda that the child's blood pressure was normal?

DR. BENDA: According to the record in 1941 the blood pressure was 120 systolic, 70 diastolic. For a

FIGURE 4. *Photomicrograph of Periadrenal Vessels.*

marked cellular infiltrations around them. These perivascular cells were polymorphonuclears, plasma cells and eosinophils. In sections stained for elastic tissue, it was obvious that part of the elastica was completely broken, with fibrinoid necrosis of the wall. The intimal proliferation was apparently secondary to the disease in the wall.

The liver showed exactly the same process, with involvement of practically every vessel. In sections of the heart the coronary arteries were almost completely occluded by fibrous tissue (Fig. 2). Throughout the myocardium there were small areas of degeneration.

In sections of the adrenal glands, the surrounding fat showed vessels in all stages of the disease (Fig. 3); at one of the poles there was a small infarct due to the vascular change. On higher magnification, the periadrenal vessels showed extreme arteritis of all layers and also fibrinoid necrosis, with prac-

mongolian that seems to me slightly elevated, since they usually have a systolic pressure not higher than 100.

DR. CASTLEMAN: Have you seen this disease in children, Dr. Gross?

DR. GROSS: Dr. Butler probably remembers a case at the Children's Hospital that might be akin to this. The child was seven or eight years old and had marked arterial lesions, but not enough to give localized inflammation of the bowel and hypertension.

Addendum. Further inquiry into the patient's history after the diagnosis of periarteritis nodosa had been established disclosed that, twenty months before death, the patient had dysentery, for which she received over 600 gr. of sulfathiazole over a sixteen-day period. The sulfathiazole blood level was under 6 mg. per 100 cc., except for one day when it reached 12.6 mg. The white-cell count was 20,000,

with 80 per cent neutrophils, and the red-cell count was about 4,000,000. Many face eruptions and multiple abscesses developed and continued to be present for the following two months. The diarrhea recurred four months later, when she was given a total of 135 gr. of sulfadiazine over a four-day period. At that time a positive culture for the Sonne type of dysentery was obtained. The cultures were negative one month later. Four months later, about one year preceding death, she received sulfadiazine for only one day, probably not more than 30 gr.

In view of Rich's^{1,2} recent studies on the role played by sensitizing antigens, especially sulfonamides, in the production of periarteritis nodosa, it is not unlikely that the patient in this case, while under sulfonamide therapy, developed acute arterial lesions, which at autopsy a year later showed various stages of healing.

CASE 30202

PRESENTATION OF CASE

A fifty-seven-year-old housewife was brought into the hospital because of pain in the left upper quadrant.

The patient was in apparent good health until six hours before entry, at which time she fell from the piazza of her home to the ground, a drop of six feet. She apparently landed on her left side and experienced severe pain in the left upper quadrant and left shoulder. She was able to stand up, however, and walked into the house, but she did this with considerable effort because of the pain. After sitting down in the house for a few minutes she felt "shaky," and during the next two or three hours had three attacks of vomiting. What the vomitus consisted of was not noted. The vomiting and deep breathing increased the pain in the left upper quadrant. There was no pain in the chest, no loss of consciousness, no loss of blood from any orifice, and no bowel movement.

The past history was negative except for an admission into the hospital some months previously for drainage of a carbuncle of the neck.

Physical examination showed a well-developed, rather obese woman who was complaining of pain in the left upper quadrant. The heart and lungs were negative. There was tenderness on pressure over the lower ribs, but no crepitus, or pain on inspiration. Marked tenderness was elicited in the left upper and lower quadrants, but none in the costovertebral angles. A nontender, movable mass twice the size of a grapefruit was palpable in the left lower quadrant, which on pelvic examination seemed

to arise from the left vault. This mass had been felt at the time of the previous admission.

The blood pressure was 100 systolic, 60 diastolic. The pulse was 70. The temperature and respirations were normal.

Examination of the blood showed a red-cell count of 4,560,000, with 80 per cent hemoglobin. The white-cell count was 24,000. The urine contained occasional white cells and innumerable red cells.

X-ray examination of the chest showed no evidence of fracture or pneumothorax. An intravenous pyelogram revealed the kidney outlines to be normal. The dye appeared in good concentration, outlining nondilated urinary passages, and no evidence of extravasation of dye into the soft tissue was seen. Plain films of the abdomen showed the pelvic mass already described.

Two abdominal taps were negative. The patient was given $\frac{1}{8}$ gr. of morphine and ice packs over the left quadrant. In the course of the next few hours the blood pressure rose slowly and the pain subsided. She was kept under close observation. In the course of the next two days the shoulder pain completely disappeared and the tenderness in the left upper quadrant practically disappeared. She was voiding well, but the urinary sediment still contained 20 to 25 red cells. Bowel movements were normal, and there was no vomiting.

On the fourth hospital day she had minimal pain in the left leg, with some swelling about the medial aspect, and there was a slight transient rise of temperature, which subsided. The next day, examination was entirely negative except for the persistent mass in the pelvis. The urine was clear, and a gastrointestinal series was negative except for a small amount of fluid in the left costophrenic angle.

On the seventh hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. ARTHUR W. ALLEN: Perhaps we might look at the x-ray films.

DR. MILFORD SCHULZ: There is nothing here except that which is confirmatory of the statements in the protocol. This film of the abdomen demonstrates the mass rising above the iliac crest. The pyelogram shows good kidney function, and I see nothing to suggest damage to the kidney.

DR. ALLEN: Does the mass change the course of the ureter in any way?

DR. SCHULZ: It is difficult to say that it does not displace it anteriorly, but it does not displace it laterally, in so far as it can be traced.

DR. ALLEN: Does the mass go into the pelvis?

DR. SCHULZ: I cannot see the lower margin where it merges with the pelvic shadows. Its lowermost reaches cannot be definitely determined.

This film of the chest and ribs shows nothing unusual. The shadow of the spleen cannot be outlined.

DR. ALLEN: In the gastrointestinal series there is mention of a small amount of fluid in the left costophrenic angle. Can you point that out?

DR. SCHULZ: That probably was a fluoroscopic observation; it cannot be seen on these films with any degree of certainty.

DR. ALLEN: We assume that, at the time of this woman's first admission, a diagnosis was made regarding the pelvic tumor — that is, some note must have been made about it because it was recorded in the physical examination. It is not stated, however, whether she had been given a house appointment to have something done about it. I assume that she had been told that it would be a good idea to come back at least for examination and possibly to have this tumor removed. Obviously it was not considered to be malignant; otherwise she would have been followed and probably brought back to the hospital earlier.

We come down then to the present illness, which started with a fall, not from a great height to be sure, but far enough to cause considerable damage. The fact that she had pain in the left upper quadrant and pain on pressure over the lower ribs is consistent with the red cells found in the urine; in other words, she probably had a contusion of the kidney. The intravenous pyelogram rules out a serious injury to the kidney, because if the kidney itself had been fractured, there would have been some extravasated dye around the kidney when the pyelogram was made. The fact that she showed a considerable number of blood cells in the urine for three or four days after injury is, I believe, sufficient evidence to prove that she did have a contusion of the left kidney. It is difficult for me to connect the contusion of the kidney and the pelvic tumor, and I am going to assume that the two lesions had nothing to do with each other, that the accident did not produce a hematuria from the standpoint of the tumor, and that the pelvic tumor was an incidental finding and was not a factor in the acute illness.

Two interesting observations make one speculate about the region of the injury. One is the white-cell count of 24,000. I assume that that was repeated and confirmed. A contusion of the kidney will not give a white-cell count of that height, nor will a great many other acute injuries, except injury to the spleen. If a patient has had an abdominal injury and has a white-cell count above 20,000 — it is frequently above 30,000 — one must be suspicious of an injury to the spleen. We do occasionally pick up a high white-cell count associated with other acute conditions of the abdomen, particularly mesenteric thrombosis and pancreatitis. The other day a patient arrived here with typical appendicitis and a confirmed white-cell count of 27,000. That is very unusual. But the high white-cell count six hours following an injury in the region of the spleen makes one suspicious that, in addition to the

contusion of the kidney, there might have been injury to the spleen.

There is another lead in the story that makes me think of the spleen. Obviously the residents who studied this patient thought of the possibility of intra-abdominal bleeding, because they tried twice to aspirate blood from the abdominal cavity, but both these attempts were unsuccessful and they quite rightly assumed that there was no intra-abdominal bleeding.

It is obvious from the record that, because of the high leukocytic count and the tenderness in the splenic region, they were suspicious that there might have been an injury to the spleen. Their suspicions were allayed, however, inasmuch as the patient got over her symptoms promptly and her white-cell count became lower.

It is quite possible, though, to have a fractured spleen that gives this picture at entry, the spleen having become tamponaded by omentum, so that there is a period of complete freedom of symptoms. We all know of a good many cases in which a fracture of the spleen temporarily stopped bleeding. A man injured on a football field, for instance, improves to such an extent that he is allowed to play a week later, only to have a burst of bleeding, at which time the correct diagnosis is usually made. A great many cases of delayed bleeding of the spleen have been recorded, particularly those by McIndoe*; and in one case a secondary hemorrhage occurred as late as twenty-eight days after the original injury. The other day in the ward I saw a boy of about twelve who had fallen on a picket fence on his left side five or six days prior to entry. At operation he had a well-tamponaded spleen, which was successfully removed. The spleen behaves differently from the other abdominal organs in that respect. Once hemorrhage has ceased from the liver, one can be reasonably sure that a secondary burst will not occur; but even though hemorrhage from the spleen has temporarily stopped, it is wiser to remove the spleen.

They do not tell us what operation was performed. I assume, however, that they did not explore this woman for the spleen. They probably assumed that all the trouble in the left upper quadrant was due to the contusion of the kidney. If the operation was done for the pelvic tumor and if they found no blood in the peritoneal cavity, they probably removed the pelvic tumor; but if they found blood, in spite of the two negative taps, they very likely investigated the spleen. If they found blood in the peritoneal cavity, I hazard the guess that they found the spleen fractured and tamponaded.

The diagnosis as I see it is a pelvic tumor of some sort. The patient was fifty-seven, which is between the age of fibroids, which occur most frequently in

*McIndoe, A. H. Delayed haemorrhage following traumatic rupture of spleen. *Brit. J. Surg.* 20 249-268, 1932.

the fourth decade of life, and that of ovarian cysts, which occur either early or late in life. I assume that the chance that this was a fibroid is better than that it was an ovarian cyst. In the acute condition she had a contusion of the left kidney with hemorrhage, and I raise the question of the possibility of a fractured spleen as well.

CLINICAL DIAGNOSIS

Fibroid uterus or ovarian cyst?
Intra-abdominal trauma?

DR. ALLEN'S DIAGNOSES

Contusion of left kidney.
Fibroid tumor of uterus.
Fracture of spleen?

ANATOMICAL DIAGNOSES

Ruptured spleen.
Uterine leiomyomas.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: Dr. Allen predicted exactly how the men on the service reacted. They did operate with the purpose of removing the pelvic tumor. As soon as they got down to the peritoneal cavity, before opening it, they could see large bluish masses through the peritoneal coat, so they realized that they would find blood in the abdominal cavity and forgot about the pelvic mass. On opening the abdominal cavity they found about 500 cc. of clotted blood, and in removing some of that they discovered that the source of the bleeding was the spleen, which had been covered with omentum and

tamponaded, just as Dr. Allen prophesied. After the spleen and all the blood had been removed, exploration of the pelvis showed that the mass was composed of two large pedunculated fibroids, which it was decided not to remove at that time.

The spleen contained two jagged tears—one about 7 cm. in length, extending in for about 1 cm., and the other about 4 or 5 cm. in length, extending into a large cavity filled with blood. On cutting the spleen another large hemorrhagic extravasation was noted, without apparent connection with an external rupture.

Do you think, Dr. Allen, that during the fall the pressure of the fibroids might have helped injure the spleen? I suppose it would have been more likely if the fibroids had been calcified.

DR. ALLEN: I had not thought of that. I had assumed that the tumor was not large enough to play a role. Possibly such was the case. It does not take much more of a blow than this woman had to fracture the spleen. If she landed just right, the fall could have done it without any help from the fibroids.

I was much intrigued by the statement in the history about the fluid in the costophrenic angle that the radiologist saw in the fluoroscopic examination; it apparently does not show on the films. If that was true, it is good evidence that there was hemorrhage from something in that region, and the usual source would be the spleen.

DR. SCHULZ: The reason that we do not see evidence of fluid on the films is, I believe, that the patient was prone or supine when the films were taken and in the upright position when fluoroscoped.

RECONDITIONING PROGRAM

THE battle of Waterloo, history tells us, was won on the playing fields of Eton, so much did the courage and discipline of his young officers contribute to the morale of Wellington's army. In a different sense, some of the future victories of our present war may have been won already on the football field of Harvard, for it is his practical experience in the reconditioning of athletes that has placed Colonel Augustus Thorndike, of Boston, formerly surgeon to the Harvard football team and more recently commanding officer of the 105th General Hospital, as director of the Reconditioning Division, created last year by the Surgeon General.

A program for this reconditioning of disabled soldiers, according to an editorial in the April 1 issue of the *Journal of the American Medical Association*, was given impetus in a two-day conference recently held at the Schick General Hospital, Clinton, Iowa, at which time the results of such a program, carried out for several months past, were demonstrated by the commandant, Colonel Dean F. Winn, and his staff.

Training for men to be returned to military duty or to be restored as quickly as possible to useful civilian occupations includes "physical reconditioning, educational reconditioning and emotional reconditioning." Physical exercises of the convalescent wounded are begun at the earliest possible time, and are based on a graduated system of calisthenics, drills, games and military training. At the same time, carefully planned programs for educational and emotional reconditioning are carried out by other well-trained personnel. In a nation whose able young manhood has almost entirely gone into the armed services, that irreplaceable segment of the population must be husbanded and guarded as the very strength of the country.

In an earlier stage of our supreme military effort, when we first began to gather our armies together and the lists of the rejected grew, emphasis was placed first on rehabilitation of the unfit, and then on rehabilitation—the correction of defects before examination, in order to minimize the number of rejections. This conservation of our effective manpower must continue, but as our forces gain battle experience, the inevitable shift must take place in favor of the salvaging of those whom battle has disabled.

More than ever before, great numbers of the disabled will be returned to full duty, others with invaluable battle experience will be made available for limited service and the majority of the remainder, it can be confidently expected, will find their places in useful civilian occupations.

CUTANEOUS SULFONAMIDE HYPERSENSITIZATION

THE indiscriminate employment of local applications of sulfonamide preparations on cutaneous manifestations is creating a menace of consid-

proportions. Not only have many cases of contact dermatitis with extensive exacerbations of the original process been produced by such applications, but serious generalized reactions have been provoked. These preparations are being used widely, both by physicians and by laymen, for eruptions without regard to whether or not they are of bacterial origin, and the number of cases with an unfavorable reaction is increasing.

Although the figures thus far presented indicate that evidences of hypersensitivity develop in only 5 per cent of those in whom such local applications have been employed,¹ in the aggregate a great amount of disability, sometimes protracted, is being produced by the complications of sulfonamide therapy. Reports presented in the literature^{2,4} indicate that hypersensitization to these drugs may be general as well as cutaneous and may be occasioned in some cases by previous oral administration, and in others by the local application of sulfonamide preparations to the skin. After this sensitization is once produced, a recurrence of the cutaneous or of the general disturbance may be precipitated either by oral administration or by local application to the skin, and it is well recognized that this hypersensitivity may be permanent. Thus the local use of sulfonamide preparations introduces a definite hazard to the later administration of sulfonamide preparations internally, perhaps for pneumonia, peritonitis or other serious infection.

Although the original cutaneous disturbance may be exaggerated by the use of a sulfonamide, it is often not recognized that the drug is the causal factor in such a flare-up, with the result that it is continued and the convalescence considerably prolonged. Furthermore, some of these patients may become sensitized to other therapeutic agents, to occupational factors or perhaps to bacteria or bacterial products, as well as to the sulfonamides. Some cases are reported to be accentuated by exposure to actinic rays, and even after the skin has become normal, subsequent exposure to sun may reactivate the cutaneous disturbance. Activation may even occur following fractional doses of roentgen rays.

These cases of hypersensitization have become so numerous and the possible consequences so dis-

turbing that the Section on Dermatology and Syphilology of the Medical Society of the State of New York at its last meeting passed resolutions "strongly disapproving the indiscriminate use of sulfonamide drugs in relatively harmless diseases of the skin which can be satisfactorily treated by equally efficient drugs" and "condemning the use of prepared dressings containing sulfonamide drugs which are sold promiscuously." Shortly after these resolutions, the *New York State Journal of Medicine* commented editorially on the matter,⁵ emphasizing the necessity of preventing or reducing to a minimum such reactions of the sulfonamides.

Cole⁶ has recently reviewed the subject; he advises that "sulfonamides should not be administered locally for more than five days because of the danger of sensitizing the individual and perhaps later precluding internal sulfonamide therapy where the situation may involve a far graver disease."

Still more recently, Tate and Klorfajn⁷ cite the British experience with sulfonamide hypersensitization. These authors indicate that dermatitis is apt to appear within fourteen days after beginning the application of sulfonamide preparations, that the person so sensitized has a group sensitivity to the various sulfonamide drugs, that there is an apparent allergy to sunlight following such a dermatitis and that desensitization can be achieved. In one case in which desensitization was attempted, the extreme hypersensitivity is shown by the fact that "when the [oral] dose was increased to 1/250 grain daily the eruption began to break out afresh." In another previously reported case the oral administration of 1/8 grain was followed in six hours by an eruption similar to the earlier rash. They advise that topical sulfonamide therapy "should be reserved strictly for cases where withholding it might endanger life or lead to deformity." Editorial comment in the same issue of the *Lancet* supports earlier conclusions that these drugs should not be used for eczematous subjects, should not be applied to any condition for longer than a week, and should be much restricted in use.

Thus, growing experience with the local use of sulfonamide preparations demonstrates that these agents should be used as topical applications only

on the advice of a physician, who should prescribe them with great care and for a short period. Furthermore, the risks of indiscriminate use should be widely publicized.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

BARRETT—James A. Barrett, M.D., of New Bedford, died April 28. He was in his fifty-ninth year. Dr. Barrett received his degree from the Maryland Medical College, Baltimore, in 1910. He was a member of the Massachusetts Medical Society, the American Medical Association, the New Bedford Medical Society and the New England Rocaigant Ray Society.

His widow, a son and a daughter survive.

BULFINCH—George G. Bulfinch, M.D., of Brookline, died March 14. He was in his ninety-sixth year. Dr. Bulfinch received his degree from Harvard Medical School in 1874. He was a member of the Massachusetts Medical Society and the American Medical Association. A son, three grandchildren and one great-grandchild survive.

COCHRAN—John J. Cochran, M.D., of Natick, died May 1. He was in his forty-eighth year. Dr. Cochran received his degree from Harvard Medical School in 1923. He was a counselor for the Middlesex South District Medical Society and a member of the courtesy staffs at the Newton and Framingham hospitals. He was a member of the Massachusetts Medical Society and the American Medical Association. His widow, two sons and two brothers survive.

CURTIN—John J. Curtin, M.D., of Waltham, died March 10. He was in his sixty-first year. Dr. Curtin received his degree from Harvard Medical School in 1909. He was a member of the Massachusetts Medical Society and the American Medical Association. His widow survives.

FAILLACE—Gaetano Faillace, M.D., of Brookline, died February 19. He was in his seventy-second year. Dr. Faillace received his degree from the University of Naples Medical School, Italy, in 1903. In 1920 he was decorated by the Italian government for outstanding professional services among Italians in Boston and New England. He was a member of the Massachusetts Medical Society and the American Medical Association. His widow, two daughters and two sons survive.

GILLESPIE—Norman W. Gillespie, M.D., of Dorchester, died April 28. He was in his fifty-sixth year. Dr. Gillespie received his degree from Harvard Medical School in 1915. He served at the Beverly Hospital, Boston City Hospital, Children's Hospital, Boston Lying-in Hospital and Walter Reed Hospital. He was a member of the Massachusetts Medical Society and the American Medical Association. His widow and two daughters survive.

JOHNSON—Herbert S. Johnson, M.D., of Stoneham, died April 29. He was in his eighty-ninth year.

Dr. Johnson received his degree from Harvard Medical School in 1883. From 1897 to 1918 he practiced medicine in Malden, during which period he was a school physician and on the staff of the Malden Hospital. In 1918, he gave up private practice to join the staff of E. I. Patch Company, manufacturers of pharmaceutical supplies. He retired in 1932. He was a former member of the Massachusetts Medical Society.

A daughter and two sons survive.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

DISTRIBUTION STATIONS FOR ANTIPNEUMOCOCCUS AND ANTIMENINGOCOCCUS SERUMS

Because of continued reductions in the demand for antipneumococcus and antimeningococcus serums, and the necessity of eliminating nonessential processing and distribution services for the duration of the war, the number of distributing stations for the above products has been reduced. The following three classes of stations will be maintained hereafter:

1. Stations regularly supplied with antimeningococcus serum and with antipneumococcus serum of the types indicated.

CITY	STATION	SERUM
Boston	Bacteriological Lab., State House	Antipneumococcus serum (Types 1, 2, 4, 5, 7, 8, 9, 14 and 16)
Worcester	Worcester City Hospital Board of Health	Antipneumococcus serum (Types 1, 2, 4, 5, 7, 8, 9, 14 and 16)
Holyoke	Providence Hospital	Antipneumococcus serum (Types 1, 2, 4, 5, 7, 8, 9, 14 and 16)
Haverhill	Hale Hospital	Antipneumococcus serum (Types 1, 2, 5, 7 and 8)
New Bedford	St. Luke's Hospital	Antipneumococcus serum (Types 1, 2, 5, 7 and 8)
Pittsfield	House of Mercy Hospital Sampson Memorial Hospital	Antipneumococcus serum (Types 1, 2, 5, 7 and 8)

2. Stations supplied with emergency stocks of antimeningococcus serum and of antipneumococcus serum (Type 1), when adequate amounts of these serums are available.

CITY	STATION
Ayer	Community Memorial Hospital
Brookton	Brookton Hospital
Gardner	Henry Heywood Memorial Hospital
Greenfield	Franklin County Hospital
Hyannis	Cape Cod Hospital
Nantucket	Nantucket Cottage Hospital

3. Stations supplied with antimeningococcus serum in certain communities not listed above, where the demand for antimeningococcus serum has been relatively frequent. The appropriate stations will be provided with this serum for emergency stock so long as sufficient serum is available and the demand is in the community.

WAR ACTIVITIES

INDUSTRIAL HYGIENE

INDUSTRIAL EYE-HYGIENE PROGRAM

The Industrial Hygiene Division of the United States Public Health Service, in co-operation with the offices of the National Society for the Prevention of Blindness, — the Joint Committee on Industrial Ophthalmology and Otolaryngology, — has been developing and carrying out a program in eyesight protection in industry. Assistant Surgeon Joseph Lo Presti was detailed to the National Society for the Prevention of Blindness in New York City in July, 1943, for this purpose.

In the past, work in this field for the most part has been directed along eye protection and safety lines. The equally important aspect of this broad field, visual job analysis, has not received the study or emphasis that it warrants. By job analysis is meant the correlation of visual skills or abilities of employees, with job performances based on various criteria, such as speed of learning rate of work, accuracy of work, amount of spoilage, absenteeism and accident proneness or frequency. In addition, no serious attempts have been made in the past to establish minimum visual requirements for different types of occupation. For these reasons the scope of the industrial eye-hygiene program was made broad enough to encompass and emphasize these aspects — in fact, to include all important aspects of vision in industry.

Because of the acute shortage of ophthalmologists and allied professional groups engaged in eye care and eye service, other methods of visual examination had to be adopted to reach a sizable number of the industrial population. Three so-called "screening devices" were found to be already available, one of which is still in the experimental stage of its development. In order to evaluate the reliability of one of these devices, namely, the Ortho-Rater, a study was conducted at Stevens Institute, Hoboken, New Jersey. A group of 336 first-term students enrolled in the drafting course were tested by means of a simplified clinical procedure and by the Ortho-Rater. From five to six minutes per subject was taken for the examination. Data from this study are now in the last stages of analysis and it may be tentatively concluded that this screening device can be practically employed in industry to study visual skills. A visit was also made to the Visual Institute at Purdue University, Lafayette, Indiana, where the Ortho-Rater was developed. Methods of obtaining vision data and correlating them with job performance were studied with a view to adopting some of them in field work.

A comprehensive industrial visual survey is now being carried out in Connecticut, operating through the Bureau of Industrial Hygiene, Connecticut State Department of Health. The objectives of this project are: to obtain a cross section of industrial vision practices in a typical, concentrated industrial region engaged largely in war work; to compare various methods of examination, particularly screening tests, for vision; to derive recommendations for methods of appraising and improving existing visual conditions of employees and to select plants that may serve as a pattern to be followed throughout the country. Six plants have been thoroughly studied to date in the Hartford region, the work being conducted through the medical department of each plant. Whenever practical, employees were tested by various screen procedures, including the Ortho-Rater and the Vector-graph; and, on one occasion, with the Telebinocular, data on visual acuity (distance and near) muscle balance, vertical and lateral (distance and near) color vision, depth perception (stereopsis) were obtained. In addition, the Industrial Eyesight Protection Appraisal Form (Publication No. 402B — National Society for the Prevention of Blindness) was filled out for each plant covered, after consultation with the person responsible for the eye program in the plant. Items checked on this form include:

Employee Data: General medical supervision and special provisions made for eye services; safety items; first-aid facilities; other special eye services, such as screening, periodic recheck and examination for particular exposures; and provision for supplying eye appliances.

Plant Job Data: Illumination, eye hazards and provision for eye safety and protection.

This appraisal form will be sent to at least 30,000 industries by the War Production Board. In line with this survey, and anticipating that industry will seek ophthalmologists to assist in correcting conditions that

may be found, the National Society for the Prevention of Blindness, with the co-operation of the chairman of the Joint Committee on Ophthalmology of the American Medical Association, is planning a seminar on industrial ophthalmology to be held in New York City at an early date. It is hoped that this will bring forcibly to the attention of the management of industries the need for an adequate eye conservation program. — Reprinted from *Industrial Hygiene News Letter* (March, 1944).

CORRESPONDENCE

MIDDLESEX UNIVERSITY SCHOOL OF MEDICINE

To the Editor: Dr. Stephen Rushmore in a letter published in the March 2, 1944, issue of the *Journal*, states that "the background of the discussion" with the Council on Medical Education and Hospitals of the American Medical Association regarding the status of Middlesex University School of Medicine is characterized in the following quotation: "The Council did not feel justified in offering any approval or even encouragement in connection with your efforts." Removed from the context of frequent discussions held by the Council with Dr. Rushmore, this sentence gives an entirely erroneous impression of the attitude of the Council.

The implication of this reference and the remainder of Dr. Rushmore's letter is that the Council is concerned with factors other than the quality of instruction in considering a school for inclusion on the list of approved medical schools, and that the Council desires to avoid additions to this list partly by refusing aid and encouragement to new schools.

Aid and encouragement have repeatedly been given to developing medical schools by the Council. Within the past year the medical school of the Southwestern Medical Foundation and the Bowman Gray School of Medicine have been approved as four-year schools. The University of Utah has expanded into a four-year medical school and partly through the help of the Council gives every promise of developing an excellent program. There has been extended correspondence with state authorities and conferences in Alabama with regard to their new four-year school. Correspondence and conferences are also being held with at least three other groups in which encouragement, advice and aid have been given by the Council.

It is notable that in each of these instances the school seems to have well-conceived plans and reasonably adequate financial and other resources and shows promise of meeting at least the minimum standards of medical education.

It is the Council's responsibility and privilege to give aid, advice and encouragement to such situations. It is clearly also the Council's responsibility not to encourage ill conceived or inadequately supported ventures into medical education. The Council has had to assume this responsibility on more than one occasion in the past and will continue to do so in the future when necessary.

OLD NAVAL MEDICAL COMMISSIONS

To the Editor: The National Naval Medical Center, of Bethesda, Maryland, is endeavoring to collect for its archives a complete set of commissions issued to Naval medical officers and signed by past presidents of the United States.

There is a small nidus now at the Center, and it is hoped to be able to build this up to completion. Through the Navy Department Library and the National Archives a few more have been located. I am asking you to insert this letter in the *Journal* with the idea that various libraries or individuals may have in their possession such old commissions and would be willing to turn them over to the Center. If such are found and the owners are so generous, there could be no more fitting enshrinement of them than their use for this purpose.

THE SURGICAL TREATMENT OF ESOPHAGEAL ATRESIA AND TRACHEOESOPHAGEAL FISTULAS*

WILLIAM E. LADD, M.D.†

BOSTON

ATRESIA of the esophagus with or without tracheo-esophageal fistula has been a baffling problem for the surgeon. If there is any surgeon who has attempted to save the lives of patients suffering from these malformations who has not had many disappointments and numerous trials and

In 1931 Rosenthal⁴ reported 255 cases, in 1933 O'Hare⁵ reported 281 cases, and by 1941 Ashley⁶ was able to collect 314 cases. From the records of the Children's Hospital in Boston can be added 72 cases, which brings the total close to 400. These figures make it apparent that atresia of the esoph-

The letters refer to the following structures: A—trachea; B—bifurcation of trachea; C—upper segment of esophagus; and D—lower segment of esophagus.

tribulations, I have not heard of him. Until very recent years this condition was considered incompatible with life. Obstetrician and pediatrician alike commonly advised that it was not worth while to attempt any remedial procedure. In the last few years, however, a few successes or partial successes have been reported from various parts of the country, and a correct point of view has been adopted: namely, that surgical intervention should be attempted. We have had a comparatively large experience with these cases at the Children's Hospital in Boston, and it may be of interest to relate our experiences in the surgical management of these anomalies.

In 1884, Mackenzie¹ attributed the first description of this condition to Durston (1670), and in 1821 Martin² published the first case report. In 1919 Plass³ reported 136 cases from the literature.

*From the Surgical Service, Children's Hospital, and the Department of Surgery, Harvard Medical School.

†William F. Ladd Professor of Child Surgery, Harvard Medical School; of Surgical Service, Children's Hospital.

agus is a much more frequent anomaly than it has usually been considered to be.

There are to be found in the literature various classifications of congenital anomalies of the esophagus. For the purposes of the present discussion, only those will be considered that have been seen in this series from the Children's Hospital. These cases may be divided into five types, as illustrated in Figure 1. Each type has minor variations. In Type I, the upper portion of the esophagus ends in a blind pouch in the region of the body of the first or second dorsal vertebra, and the lower segment of the esophagus begins again in a blind pouch at the level of the fourth or fifth dorsal vertebra. In Type II, the upper segment of the esophagus ends in a fistulous tract entering the trachea just above its bifurcation, whereas the lower segment is much the same as in Type I. In Type III, the upper segment ends blindly as in Type I, whereas the lower segment is connected to the trachea just above its bifurcation by a fistulous tract. This type and Type IV are by far the commonest in the reports.

of the literature as well as in our own experience. Type IV is similar to Type III except that the fistulous tract of the lower segment enters the trachea at its carina instead of just above its bifurcation. In Type V, both the upper and lower segments communicate with the trachea, as shown in the diagram. These types may be quite accurately diagnosed and are important to consider when one is deciding on his plan of treatment. For any form of treatment to be successful, it is of paramount importance to make the diagnosis as early as possible and to have the infant transferred to a hospital equipped to care for this kind of patient. This

without tympany, according to the variety of the malformation.

Obviously, in Types I and II there is no possibility for air to enter the stomach and intestines, so that one finds the abdomen sunken and without tympany. In Types III, IV and V, however, every time the infant breathes he forces air into the stomach and intestines. In these types, therefore, the abdomen is moderately distended and extremely tympanitic and sometimes contains large amounts of air if the tracheoesophageal fistula of the lower end of the esophagus is a large one.

With these symptoms and findings, the next step

FIGURE 2. *Atresia of the Esophagus, Type I.*

These roentgenograms were taken preoperatively. Note the complete absence of air in the stomach and intestine.

early diagnosis and allocation of the patient is usually the responsibility of the obstetrician or pediatrician.

The diagnosis may be suspected when the newborn infant has an excess of saliva in the mouth and perhaps an associated cyanosis. The next suggestive symptom to present itself is immediate vomiting after the first and any succeeding feeding. If the infant is not put to the breast or is not offered the bottle, he may appear quite normal after the excess saliva has been suctioned from the pharynx. Examination of the chest, however, usually discloses moist rales caused by aspiration of saliva or fluid given. These rales are apt to be most marked at the right apex, possibly for the reason that in the dorsal position aspirated fluid enters the right main bronchus and then the bronchus to the right upper lobe more easily than any other part of the lungs. Abdominal examination shows the abdomen to be either distended with air and tympanitic or completely flat

in the investigation is to insert a small rubber catheter in the esophagus. If this meets obstruction at 10 to 12 cm. from the lip margin, the diagnosis of esophageal atresia is practically confirmed. It is well, however, to check this finding by a roentgenologic examination to make sure that the catheter has not curled up in the pharynx or esophagus. The administration of barium is undesirable regardless of the type of malformation. If the case is of Type II or V with a fistula between the upper segment and the trachea, the administered barium goes directly into the lung and causes an aspiration pneumonia or an increase in the already existing one. The only reason for which a contrast medium is desirable is to determine the presence or absence of a tracheal fistula in the upper segment of the esophagus. To gather these data, a small amount of lipiodol should be used during a fluoroscopic inspection. If a large amount is used and it is not watched with the aid of the fluoroscope, some of it may spill over the top, so

to speak, be aspirated and confuse the picture. A roentgenologic examination of the abdomen is also of advantage in differentiating the varieties of the malformation. If this examination shows no air in the abdominal viscera, one must be dealing with Type I or II, if, on the other hand, the ex-

amination shows a serious nature and that some are even incompatible with life without relief by major surgical procedures.

TABLE 2 Site of Fistula in Cases of Types III and IV

SITE OF FISTULA	NO. OF CASES
At carina	16
Above carina	
00-0.5 cm	9
1.6-1.0 cm	3
1.1-1.5 cm	4
1.6-2.0 cm	2
Over 2.6 cm	1

It can also be stated, however, that there were 23 cases in this series with no accompanying malformations.

There is a considerable variation of the location of the fistulous opening into the trachea, as seen in Table 2 which lists the cases of Types III and IV.

TABLE 3 Distance between Esophageal Segments

DISTANCE	NO. OF CASES
Ends overlapping	1
0.0 to 0.5 cm	5
0.6 to 1.0 cm	7
1.1 to 1.5 cm	6
1.6 to 2.0 cm	4
2.1 to 3.5 cm	2
8.0 cm	1

Table 3 shows the variation of the distance between the two segments of the esophagus as noted in the post-mortem findings. This variation be-

mination shows the stomach and intestines filled with air, one can rest assured that one is dealing with Type III, IV or V. The careful records kept by Dr. Sidney Farber in the Pathology Department have made it possible to collect data that are not only of interest but of value in helping to formulate the plan of treatment.

From post-mortem findings it is apparent that these anomalies of the esophagus are frequently associated with anomalies of other parts of the body, as demonstrated by Table 1, which shows the type

comes an important factor when one is considering the selection of the type of operation best suited for a given case.

These variations are not so important, however, as the two fundamental causes of death, which are pneumonia and starvation. Of these two, pneumonia is the more difficult to combat. Any operation that fails to prevent aspiration of saliva or fluid given either by mouth or by stomach is usually doomed to failure.

There have been numerous plans of surgical approach to this problem, some of which come close to meeting the requirements for combating these two main causes of death. The operation devised by Gage and Ochsner,⁷ which consists of tying off the cardia and doing a gastrostomy and marsupialization of the upper segment of the esophagus, has much to recommend it. It prevents the constant aspiration of secretion from the upper segment and allows feeding by gastrostomy without danger of reflux into the lungs through the tracheoesophageal fistula. Carter's⁸ objections to the operation are that it leaves a long esophageal pouch connected to the trachea and that the esophagostomy opening is too far removed from the gastrostomy. The first objection appears to be valid, since this pouch is certain to be a source of aspiration or infection at some later period. Our experience leads us not to concur with the second objection, since we have found that liquid and food pass through a long skin tube quite as readily as through a short one. We do, however, have another objection to the operation of Gage and Ochsner. This is that the ligature around the cardia may slough through and result in either leakage or recanalization of the esophagus. This catastrophe has indeed happened in 2 of our cases under a slightly different condition: namely, when the esophagus has been tied higher up in the mediastinum. To obviate leaving a long lower-segment pouch of the esophagus, Gamble⁹ devised an operation that has the obvious drawback of a permanent tracheal fistula. He tied off the cardiac end of the stomach and brought the esophageal end of the stomach connecting with the esophagus out onto the abdominal wall. Leven¹⁰ in 1936 advocated an operation embodying much the same principles as did that of Gage and Ochsner but with a different technic. He later abandoned this plan, which he had used with 2 patients, both of whom died of pneumonia.

Carter⁸ devised an operation that consisted of bringing the lower end of the esophagus down through the diaphragm and leading it up onto the abdominal wall. This was done through an abdominal approach. We have the same reason for objecting to Carter's operation that he himself uses against the operation of Gage and Ochsner: namely, the leaving of a long lower-segment pouch of the esophagus. It should also be noted that his patient died of pneumonia after eight to nine weeks of life. Regardless of his report that the pneumonia was an incidental development independent of the remaining esophageal pouch, it is still impossible to

believe that the presence of such a sac is desirable or without danger.

The next operative procedure to be considered is that of a direct attack on the site of the malformation through the back extrapleurally, tying off the tracheal esophageal fistula and marsupializing the ends of the lower and upper segments in the back. This plan was originally advocated by our former associate, Dr. Charles G. Mixter, and it was performed on several occasions by various members of the surgical staff of the Children's Hospital. One patient who was operated on according to a modification of this plan by my associate, Dr. Thomas H. Lannian,¹¹ survived for forty-seven days but eventually succumbed to pneumonia, pleuritis, mediastinitis and septicemia. This operative plan has some advantages; it leaves no blind esophageal pouch, takes care of salivary secretions and provides for feeding, and leaves open the possibility of a later end-to-end anastomosis. It has the disadvantages that the esophagostomy is in a position in which it is hard to handle and that it is difficult to prevent the development of mediastinitis, which has ultimately been a factor in the death of every patient in whom we have employed it. We have abandoned its use.

End-to-end anastomosis through an extrapleural approach in the back is without question the operation of choice in all patients in whom the two ends of the esophagus are close together. It closes the tracheoesophageal fistula, takes care of the salivary secretions, provides for feeding and theoretically restores the esophagus nearer to normal than does any other plan. The technical difficulties are three: the discrepancy in size of the two esophageal segments, the distance between the segments and the anatomic structure of the esophagus itself. The first two of these obstacles are variable according to the findings in each case. The third one is constant but should be surmountable provided that the other two factors present only minor difficulties. Until recently attempts by various members of the Children's Hospital staff at direct end-to-end anastomosis in cases of tracheoesophageal atresia have met with no success. Through a modification of our technic in suturing, the patients in 2 cases of direct anastomosis are doing well. The esophagus is reached by the same extrapleural approach that we have been using for the last four or five years for tying off the tracheoesophageal fistula. An L-shaped incision is made between the inner border of the scapula and the spine on the right side and run underneath the inferior angle of the scapula (Fig. 5). By this incision the third, fourth and fifth ribs are exposed in the back. A section of the fourth rib is excised subperiosteally, and the third and fifth ribs are cut to allow for retraction. The pleura is then stripped off the thoracic cage until the azygos vein is seen. One next identifies the communicating branch of the azygos vein, and it is tied and cut.

This acts, as a rule, as an excellent landmark for the esophagus. Both segments of the esophagus are then identified. The tracheoesophageal fistula of the lower segment is tied and cut. After the tracheoesophageal fistula has been eliminated and the lower segment of the esophagus has been mobilized, the upper end of the esophagus is likewise identified and mobilized, care being taken not to injure the

placed between them to invert the edges. The anastomosis thus having been completed, the ends of the ribs that have been cut are approximated. The periosteum of the rib that has been excised, is likewise sutured together, and the muscle layers of the back are reunited and the skin closed over a small drain that has been left in between the pleura and the thoracic cage. During the whole procedure the

FIGURE 5. Operation for Direct Anastomosis of Esophagus.

shows the incision between the inner border of the scapula and the spine; 2 shows the third, fourth and fifth ribs exposed with section of the fourth rib excised subperiosteally; 3 shows the pleura and lung retracted and the communicating branch of the azygos in (a) lying over the esophagus; and 4 shows the communicating branch of the azygos vein (b) cut, and the esophagus and tracheoesophageal fistula exposed and ready for tying and cutting.

neumogastric nerve. Four stay sutures are placed near the end of each segment, as shown in Figure 6. Each of these sutures starts about 1.5 cm. from the end of the segments of the esophagus. These four sutures are of great importance since they give a firm attachment to tissue, which is by nature a loose structure and allows ordinary sutures to pull out easily. The catheter, which has already been inserted in the upper segment of the esophagus, is run through the lower segment into the stomach and left there. One next uses four or five interrupted sutures to approximate the mucous membrane of each end of the esophagus. The four stay sutures are tied, and four interrupted mattress sutures are

pleura has not been opened and there is no problem of pneumothorax. This approach is preferable to that on the left side, which has been advocated by Haight and Towsley,¹² but whether one reaches the esophagus through the right or the left side at the back is a matter of preference and is of no great importance.

The patient is fed through the indwelling catheter for a week or ten days, when a gastrostomy is performed and the esophageal catheter is removed. In the 2 surviving patients treated by this technique we have avoided the difficulties of a leak in the anastomosis, which was experienced by Haight in his successful case. Although this is the operation of choice in

selected patients in whom the two ends of the esophagus are close together, it is an extremely difficult operation and is probably unsafe in patients in whom the two ends of the esophagus are far apart.

As previously stated, it was apparent in our experience that pneumonia was the usual factor that prevented survival. It was also presumed that aspiration was the major cause of the pneumonia.

FIGURE 6. Operation for Direct Anastomosis of Esophagus.

1 shows the placement of the stay sutures; 2 and 3 show the two ends of the esophagus brought together by the stay sutures, and the placement of the interrupted sutures to the mucous-membrane sutures; 4 shows the completion of the mucous-membrane sutures, and the stay sutures being tied; 5 shows the method of placing the mattress sutures for the sake of inversion after the other sutures have been tied; and 6 shows the completed anastomosis with the inlying catheter running through it.

For these cases we have adopted a different technic, which we have been following for a little more than four years, with 8 patients now living.

It is interesting to note that Leven,¹³ at almost the identical time, came to the same conclusion about methods of attacking this problem and adopted principles identical with ours with only minor variations of technic. So far as I know, he has the oldest living patient with esophageal atresia and a tracheoesophageal fistula, his patient being twenty-four hours older than our oldest living one. In a recent personal communication he states that he has 4 additional patients living who have been operated on according to principles similar to those about to be described.

It therefore seemed logical to adopt a surgical plan that would have for its first objective the elimination of the conditions favoring aspiration. After this had been accomplished, the next step was to provide for feeding, and the third step was the construction of an anterior thoracic esophagus.

In patients with Types III and IV in whom the ends of the esophagus are too far apart to warrant an attempt at direct anastomosis, the esophagus again is approached in the same manner as just described for a direct anastomosis and the point of the tracheoesophageal fistula is identified. The fistula is then tied and cut. In some earlier cases only the tracheoesophageal fistula was tied, and in 2 cases the ties cut through the esophagus, the

esophagus was recanalized and the fistula was re-established (Fig. 7). One of these patients died from drowning after a gastrostomy feeding. In the other case it was recognized by the symptoms

FIGURE 7. Post-Mortem Specimen Showing a Recanalized Esophagus.

The tie that was originally around the esophagus is within its lumen.

that the patient was in the same condition. The wound was reopened, the fistulous tract was cut and the ends were tied off. The patient is in the process of having his anterior thoracic esophagus constructed.

After the tracheoesophageal fistula has been obliterated by tying and cutting, the chest wound is closed as before. In a few days a gastrostomy is done, which allows feeding to be carried on successfully without the danger of the milk's being regurgitated into the lung. During this interval the patient is kept in a moderate Trendelenburg position and either continuous or intermittent suction is applied to the pharynx to prevent the aspiration of saliva.

The third stage of the operation consists of bringing the upper segment of the esophagus out in the

neck. This is accomplished by making a small transverse incision 1.5 cm. above and parallel to the clavicle, the inner end of the incision starting at the midline and the incision being carried laterally to the left for a distance of 3.5 cm. With the head extended and rotated to the right, the trachea is displaced laterally and does not interfere with the identification or freeing of the esophagus. In some cases, to give more room, the lower end of the sternocleidomastoid muscle is cut. There is usually a fibrous band extending downward from the lower end of the upper segment of the esophagus into the mediastinum. This must be cut in the mediastinum before the blind end can be delivered. After its delivery it is opened, the musculature of the esophagus is sutured to the subcutaneous tissue and the mucous membrane is approximated to the skin. The esophagostomy allows for the free discharge of saliva over the neck and avoids the danger of aspiration pneumonia.

After these procedures have been completed one can wait for an indefinite period before constructing the anterior thoracic esophagus. In our first successful case, considerable time was spent in trying to connect the esophagostomy to the gastrostomy by

FIGURE 8. Fifth Step of the Operation in Types III and IV.

1 shows the tube graft with the Thiersch graft underneath it, and the marking of the skin around the esophagostomy for the transfer of the lower end of the tube graft (A, B and C).

various devices. Although this has been successfully done in adults, it was eventually abandoned as being impractical in infants.

The original gastrostomy in our oldest patient was changed to the Ssabanejew-Frank type and connected to the skin tube of the anterior thoracic

esophagus. In the next patient, now over two years old, the original gastrostomy, which was of the Witzel

method has consisted of making two parallel incisions, elevating the flaps of skin and suturing the

FIGURE 9. Fifth Step of the Operation for Types III and IV.

A V-shaped incision (A', B', and C') is made over the esophagostomy opening as shown in 2. The points A, B, and C, marked in Figure 8, are then sutured to A', B', and C', respectively. The flap that is turned down over the esophagostomy opening is sutured to the undersurface of the tube graft.

type, was closed and the whole of the lower segment of the esophagus was brought down through the diaphragm and out of the abdominal incision onto the chest wall. This was done in two stages. The first stage consisted of the freeing of the esophagus by an extrapleural approach through the right side of the back. The second stage was a laparotomy, during which the cardiac end of the stomach was freed and the lower segment of the esophagus was brought down through the esophageal hiatus and out of the abdominal incision. This segment was next tunneled under the skin of the chest, brought out through a suitable-sized incision and stitched to its skin edges. This procedure is much like that recommended by Carter⁸ except that no segment of the esophagus is left in the mediastinum. Although we have a patient still living who was operated on two years ago by this plan, its use has been abandoned on account of the difficulty of regurgitation.

The next problem is the construction of the skin tube and the establishment of the continuity of the esophagus with the stomach. This has been done in several ways by different surgeons. The simplest

FIGURE 10. Fifth Step of the Operation for Types III and IV.
5 shows the incision for making the epithelial-lined tube.

edges together with the skin inside. The raw surface is then covered by undermining the skin on either side of the skin tube and bringing these flaps over the skin tube. The objection to this plan is the requirement of tension sutures, which are undesirable, and the fact that the newly constructed skin esophagus must necessarily be compressed, making it difficult for food to pass through it. To obviate these disadvantages, other surgeons have covered

of the neck over the esophageal opening, as shown in Figure 9. After this tube graft has acquired its

FIGURE 11. Fifth Step of the Operation for Types III and IV. It shows the construction of the epithelial-lined tube, which is to be covered by the tube graft, as shown in Figure 12.

the raw surface of the skin tube with a free graft. Although this has proved satisfactory in adults, it was the disadvantage in infants of requiring pressure while the graft is taking, and it also leaves a thin-walled tube, which is subject to leakage or injury. To avoid these objections, the following plan was adopted. First, a tube graft of appropriate length is raised on the right side of the chest, starting in the right axilla and running down onto the abdominal wall in front of the iliac crest. The raw surface under this tube is covered by a Thiersch graft to avoid pulling over the skin of the chest wall (Fig. 8). Some three weeks later the lower end of this tube graft is freed and sutured to the skin

FIGURE 12. Fifth Step of the Operation for Types III and IV. It shows the tube graft being placed over the epithelial-lined tube and being sutured in place.

new circulation from the neck, the epithelial-lined tube that is to act as an esophagus is constructed and covered by the tube graft, as shown in Figures

FIGURE 13. Final Step of the Operation for Types III and IV. It shows the second tube graft, which is to be used for the covering of the lower part of the epithelial-lined tube.

10, 11, and 12. These procedures leave an epithelial-lined tube with a good skin covering carried to within a few centimeters of the gastrostomy opening (Fig. 13).

The next step is similar to what was carried out to make the upper portion of the skin tube. A tomy opening. An inverted skin tube is constructed to include the gastrostomy opening and to connect

small tube graft is raised in the left flank with its end transferred to a position just below the gastrostomy with the upper skin tube, as shown in Figure 1. The tube graft is used to cover the raw surface

is previously done above. Figure 15 shows the anterior thoracic esophagus completed in the oldest patient, who is now over four years of age.

Since 1939 we have operated on 34 patients according to our present method (Table 4). Of these patients, 6 have had primary anastomosis of the esophagus and 2 are living. Twenty-eight patients

patient, who also had a Type IV lesion, died a week after the operation with pneumonia as the main cause of death, but this infant also had a congenital heart lesion. A third patient, whose malformation was of Type I, died a month after the operation. There was considerable technical difficulty with the gastrostomy on account of the extremely small size

FIGURE 14. Final Step of the Operation for Types III and IV.

2 shows the flaps being elevated to form the epithelial-lined tube; 3 and 4 show their being sutured to the previously made epithelial-lined tube; and 5 shows the raw surface's being covered by the tube graft and being sutured.

have had the three-stage operation consisting of obliteration of the esophageal fistula and gastrostomy and esophagegostomy; 9 of these patients are living.

A few examples of the causes of death in the patients not living are of interest. The cause of one death appeared to be the usual pneumonia, the effects of the operation and, as a contributing factor, an open intraventricular septum and other cardiac anomalies. This was a Type IV anomaly. A second

of the stomach. The blind end of the lower segment of the esophagus was a little over a centimeter above the diaphragm, making a primary anastomosis of the esophagus out of the question. In a fourth case, one of Type IV, death occurred on the fifth postoperative day with pneumonia as the main cause. In a fifth case, of Type V, the patient died on the fifth day of life. Death was due to pneumonia and failure to recognize a fistula extending from the upper esophageal segment to the trachea,

A sixth patient, with a Type IV anomaly, did extremely well for a month after the tracheoesophageal fistula was tied off, the upper segment of the esophagus had been marsupialized and a gastrostomy had been performed. He gained in weight steadily and

FIGURE 15 *Functioning Anterior Thoracic Esophagus in a Child Four Years Old Who Takes a Liberal Diet.*

was in excellent condition, but died suddenly of asphyxia that at post-mortem examination was found to be due to regurgitation of fluid fed through a recanalized tracheoesophageal fistula. The death of a seventh patient (Type IV) was most disappointing. This patient had done extremely well for three months and a half, when he became infected by an epidemic enteritis from which he died within twenty-four hours of its onset.

Of the 11 living patients, the oldest is now over four years of age. She eats a moderately varied diet and indulges in fairly normal activities for a child of her age. Her only complaint consists of occasional attacks of pain in the lower end of the new esophagus, apparently due to contraction of the gastrostomy opening, which requires dilatation. The next oldest patient is a little over two. The anterior thoracic esophagus has been completed, but there is a pin-sized leak that is slow in healing. The third oldest patient is seventeen months old, is in excellent health and is in the process of having his anterior thoracic esophagus constructed. The other 6 patients, who have been operated on by the

three-stage method with the anticipation of constructing an anterior thoracic esophagus, are seven months, five and three-quarter months, five and a half months, three and three-quarter months, two and a half months and one and a quarter months old, respectively. They are all doing well and gaining in weight regularly. It is worthy of note that the last two patients were born a few weeks prematurely weighing 4 pounds, 6 ounces, and 4 pounds, 10 ounces, respectively.

Of the 2 living patients on whom a direct anastomosis was done, one is a little over seven months old and the other is five months old. The older of these is being fed entirely by mouth, is gaining in weight and is doing well. The younger patient is still being fed partially by mouth and partially

FIGURE 16 *Seven-Month-Old Baby with a Direct Anastomosis. All feeding is done by mouth, and the infant weighs over 15 pounds.*

by gastrostomy. He has had some respiratory difficulty, but this is improving and he is gaining in weight (Fig. 16).

SUMMARY

From our experience and that of others, it seems fair to conclude that atresia of the esophagus with or without tracheoesophageal fistula should no longer be considered as a hopeless condition carrying with it a 100 per cent mortality. It also seems justifiable to predict that if obstetricians and pedi-

aticians are on the alert for making an early diagnosis, the mortality will be further lowered.

It should also be stated that the surgical methods for combating this condition are subject to change. At the present time, however, primary anastomosis of the esophagus appears to be the operation of choice when the two ends of the esophagus can be approximated without too much tension. In other cases, where the ends of the esophagus are far apart, the three-stage operation with the ultimate construction of an anterior thoracic esophagus is a safer operation. The last 5 patients operated on according to this plan are living and doing well.

I am indebted to Dr. Sidney Farber for his careful post-mortem observations, and to Dr. Tague C. Chisholm for reviewing the literature and tabulating the statistics.

HEREDITARY HEMORRHAGIC TELANGIECTASIA*

An Analysis of Capillary Heredopathies

KARL SINGER, M.D.,† AND WILLIAM Q. WOLFSON, M.D.

WALTHAM, MASSACHUSETTS

THE hereditary hemorrhagic diatheses constitute an interesting group of relatively rare conditions that, in general, may be considered to fall into three main groups. The first group includes conditions characterized by hereditary disturbances in the plasma components of the hemostatic mechanism, and is exemplified by hereditary hypofibrinogenemia and probably hemophilia. In the second group are placed those hereditary conditions showing alteration in the platelets. This alteration may be a quantitative diminution (hereditary thrombocytopenic purpura) or a qualitative change in platelet function (thrombasthenia). The third group comprises the hereditary disorders of capillary structure and functions — the capillary heredopathies. They are transmitted by, and appear in, both sexes. All hitherto described capillary heredopathies present a normal platelet count and normal clotting and prothrombin times. The usual classification of these disorders is in terms of the results obtained by various functional tests, such as the bleeding time and the tourniquet test. Three capillary heredopathies are ordinarily considered well-defined entities; these are pseudohemophilia, hereditary familial purpura and hereditary hemorrhagic telangiectasia.

Pseudohemophilia (Glanzmann,¹ Morawitz, and Jürgens² and von Willebrand and Jürgens³) is characterized by an increased bleeding time. The tourniquet test may be positive or negative, and it is claimed that in some cases clot retraction is defective. The latter findings, however, vary not from case to case but from family to family. Epistaxis, spontaneous ecchymoses, prolonged bleeding after operation, spontaneous bleeding from mucous membranes and an onset in early life with decreasing severity in later life are the usual clinical manifestations.

Hereditary familial purpura simplex (Davis⁴) is characterized by the appearance of spontaneous ecchymoses and a positive tourniquet test but a normal bleeding time. Further clinical observations included a low incidence of other forms of spontaneous bleeding and frequent association with rheumatoid arthritis and rheumatic fever. A family described by Davis⁴ had hereditary hemorrhagic telangiectasia as well as hereditary familial vascular purpura.

Hereditary hemorrhagic telangiectasia (Rendu,⁵ Osler^{7,8} and Weber⁹) is the third of the well-demarcated capillary syndromes. It is characterized by a normal bleeding time and typical gross disseminated capillary abnormalities. A negative tourniquet test is usually included as a diagnostic criterion. The characteristic angiomas are composed of

*From the Department of Clinical Pathology, Middlesex University School of Medicine.

†Professor of clinical pathology, Middlesex University School of Medicine.

dilated small vessels that histologically comprise a single layer of endothelium with a conspicuous deficiency of the muscular and elastic layers of the vessel wall.¹⁰⁻¹² Clinically, bleeding, particularly epistaxis, usually begins at about the second decade of life. Visible telangiectases, which in most cases bleed with minimal trauma, appear somewhat later. Telangiectases are most frequently found in the nose and mouth and on the face, neck and hands. All other organs, including the viscera, may be involved. In one family not only a tendency to telangiectasia but also a monosymptomatic location in the lung was inherited.¹³ Severe cases are associated with hypochromic microcytic anemia, splenomegaly and, more rarely, hepatomegaly.

Any attempt to classify hereditary hemorrhagic disorders in general, and capillary hereditary pathies in particular, encounters certain difficulties. These are partly due to uncertainties in the interpretation of the mechanism of the various tests on which separation of these syndromes is based, and partly due to coexisting combinations of various types in the same family (Fig. 1).¹⁴ For example, it has been noted that some pseudohemophilic families show a positive tourniquet test as well as a prolonged bleeding time, whereas others show only a prolonged bleeding time. Some families are said to have deficient clot retraction, whereas in others the clot retraction is normal. Furthermore, combinations of thrombocytopenia with capillary disorders may be seen.¹⁵

This paper describes a family in which the typical lesions of hereditary hemorrhagic telangiectasia, together with a positive tourniquet test, were present in all members examined.* Since the presentation of rare and unusual syndromes is chiefly of value for the light that it throws on general pathologic physiology, an attempt is made to discuss the underlying mechanisms of the capillary hereditary pathies.

CASE REPORTS

CASE 1. R. Z., an 80-year-old woman, came under observation because of repeated spontaneous epistaxis over a period of 40 years. Cauterization of the nose 7 years previously had afforded relief for only 6 months. For 30 years she had noted red spots on the ends of the fingers and on the mucous membranes of the mouth. There were no spontaneous ecchymoses, nor was there increased bleeding after minor injury. Before the menopause, which occurred at the age of 45, the menses had not been unusual except for slight hypermenorrhea. A careful investigation of the nutritional background revealed a diet that was qualitatively and quantitatively adequate. There had been occasional attacks of migraine at the menstrual period; these ceased at the menopause. The history was otherwise noncontributory, except for some episodes of acute arthritis 20 years previously.

Physical examination revealed a well-developed, well-nourished woman who looked and acted much younger than her age. On the roof of the mouth, the frenulum of the tongue, the palm, the fingers and to a lesser extent the forearm were found the typical lesions of telangiectasia. The mouth and teeth were in excellent condition. Except for Heberden nodes on the fingers, no pertinent physical findings were noted.

While the patient was under observation the temperature varied from 97.0 to 98.6°F., and the pulse from 70 to 80.

*We are indebted to Drs. James Burns and Ralph Manning for permission to report these cases.

Several blood-pressure determinations ranged closely about 140/60. Repeated urinalyses were negative.

The red-cell count was 4,100,000, with 3 per cent reticulocytes, and the hemoglobin was 14 gm. (90 per cent). The white-cell count was 9100, with 5 per cent staff cells, 67 per cent neutrophils, 21 per cent lymphocytes, 4 per cent monocytes and 3 per cent eosinophils. The color index was 1.08. The hematocrit was 38 and the mean corpuscular volume 92 cubic microns. The platelet count was 220,000 (Rees-Ecker method). Clot retraction was normal. The prothrombin time was 20 seconds (normal, 18 seconds) (Quick method). The bleeding time was 2 minutes (Duke method), the clotting time 4 minutes (Lee-White method) and the sedimentation rate 9 mm. in 1 hour (Wintrobe method).

A tourniquet test was performed by placing a blood-pressure cuff on the upper arm and inflating it to halfway between the systolic and the diastolic pressure. After 15

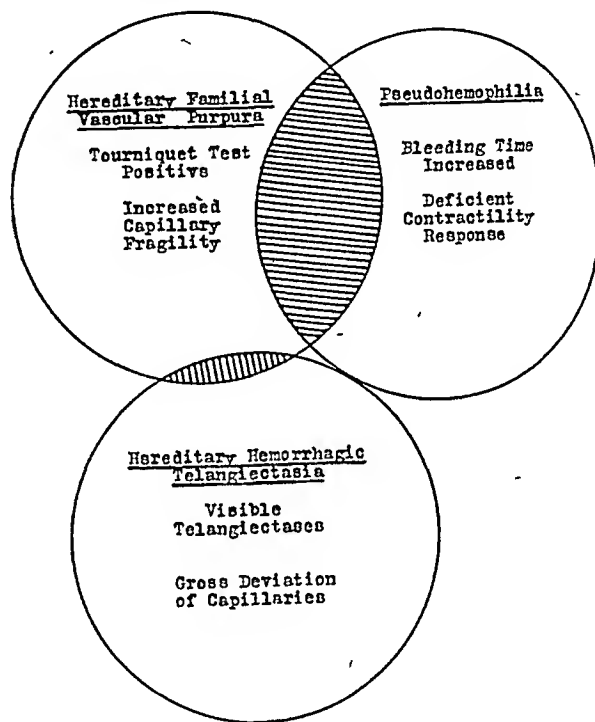

FIGURE 1. Diagram Illustrating the Various Pure Types and the Reported Combinations of Hereditary Capillary Syndromes. The shaded areas represent the observed combinations and their respective frequencies. An association of increased bleeding time (pseudohemophilia) and gross deviation of capillaries (telangiectasia) has not yet been reported.

minutes, the number of petechiae were counted in a circle 2.5 cm. in diameter that had been drawn on the flexor surface of the forearm 4 cm. below the bend of the elbow. No petechiae were found in this area before beginning the test, and 60 to 70 were found after testing; the test was therefore distinctly positive, since 10 petechiae are considered to be the upper limit of normal.¹⁶

Further investigation revealed a strong familial and hereditary tendency to telangiectasia (Fig. 2). The patient's father had had marked telangiectasia and epistaxis, which was occasionally severe enough to lead to fainting. Because the patient left home at an early age, no information about her father's further history was available, nor could information about earlier generations be secured. There were two sons, the younger of whom died of diphtheria at the age of 2. The elder was asymptomatic until the age of 22, when epistaxis commenced. It is interesting to note that he had been able to play

the trombone until this time but was then forced to stop because it induced epistaxis. Typical telangiectases developed later, but bleeding never became so severe as that of the mother. This son died at 55 of peritonitis.

There are reports on 66 members of the family (33 males and 33 females), 16 of whom (8 boys and 8 girls) have telangiectasia (a certain number are too young to show lesions as yet). The sex incidence, therefore, is not remarkable.

Certain other interesting details were encountered. In one line, telangiectasia was present in the first generation but not in the second or third, and reappeared in the fourth generation. This so-called

In comparing Case 2 with Case 1, it was noted that the tendency to bleed from the visible telangiectases and the tendency to easy bruising were more marked in the former. Epistaxis was more marked and the tourniquet test was somewhat more strongly positive in the latter. In Case 3 (below) similar findings were present, but the tendency to easy bruising was even more prominent and the tourniquet test was the most strongly positive of the 3 cases.

CASE 3. C. M., a 46-year-old housewife, reported repeated spontaneous epistaxis beginning at the age of 8. Telangiectases on the hands were first noticed at 20, and increased in number with increasing age. The patient bruises

FIGURE 2. The Family Tree.

skipping has been described by Fitzugh.¹⁷ One instance of intermarriage within the family was noted. In this case, a girl of the third generation with telangiectasia married her first cousin, of the third generation, who did not have telangiectasia. There were two children—a hyperature stillbirth and an infant with complete spina bifida. The association of hereditary hemorrhagic telangiectasia with anomalies of the vertebral column has previously been reported.¹⁸⁻²⁰

Unfortunately, this family had become spread throughout the United States and only 2 other members (Cases 2 and 3) could be examined.

CASE 2. T. C., a 49-year-old, married woman has repeated spontaneous epistaxis since the age of 11. Telangiectatic lesions appeared on the hands in the 30th year, and much more extensive distribution developed at the menopause. There have been no spontaneous ecchymoses or increased bleeding after small injuries, but the patient bruises easily. At the age of 37 she had "arthritis," which was relieved after tooth extraction, and she had hay fever, asthma and urticaria. The menses were regular and were not remarkable except for some hypermenorrhea. The menopause occurred at the age of 45.

Physical examination revealed the typical lesions of hereditary telangiectasia on the face and hands and in the mouth. Telangiectasia was also found under the nail of the left 5th toe. The physical findings were otherwise noncontributory. The red-cell count was 5,280,000, and the hemoglobin was 15.9 (92 per cent), giving a color index of 0.9. The white-cell count was 7500, with a normal differential pattern. The platelet count was 250,000. The bleeding time was 2½ minutes, and the clotting time 4 minutes. A tourniquet test was distinctly positive.

A number of siblings have migraine and the patient herself had had a few attacks in early adulthood. Her 3 children have epistaxis. The youngest son, aged 25, has already developed telangiectasia on the hands.

easily. She occasionally bleeds from telangiectases on the tongue and lips. The menses are regular, but there is marked hypermenorrhea.

The patient married her first cousin, who, although in the direct line of descent, was not afflicted with telangiectasia. There were three pregnancies. One was terminated by spontaneous miscarriage, one child of 13 pounds was stillborn, and the other lived only 3 days after birth. The description of one of these children is compatible with complete spina bifida.

Physical examination revealed a well-developed, well-nourished woman who presented the typical lesions of hereditary telangiectasia on the hands, tongue, lips, face and the mucous membranes of the buccal cavity. No other significant physical findings were elicited.

The red-cell count was 4,600,000, the hemoglobin 14.3 gm. (92 per cent), the color index being 1.0. The white-cell count was 7800, with a normal differential pattern. The platelet count was 325,000. The bleeding time was 2 minutes, and the clotting time 3½ minutes. A tourniquet test was strongly positive.

DISCUSSION

Occurrence of Positive Tourniquet Tests in Hereditary Telangiectasia

The outstanding peculiarity of this family is the occurrence of a positive tourniquet test in a syndrome in which a negative tourniquet test is ordinarily considered a diagnostic criterion. For example, the tables given for the differential diagnosis of the hereditary hemorrhagic diatheses in current textbooks of hematology²¹⁻²³ include this as an important item. Although only 3 members of the family could be examined, the occurrence of the unusual combination of a positive tourniquet test with telangiectasia in all of them makes it likely that both abnormal capillary manifestations were present on a hereditary basis.

A review of the literature on hereditary hemorrhagic telangiectasia of the last ten years shows that most of the authors reporting cases^{12, 24-31} do not mention having performed a tourniquet test or suction test. Five authors^{10, 18, 32-34} report performing tourniquet tests in 9 cases. The result was negative in 8 cases and questionable in 1.

The only report of an unequivocally positive tourniquet test that can be found is that of Davis,^{4, 5} who in his study of hereditary familial purpura simplex reports a family with spontaneous ecchymoses, a positive tourniquet test and typical lesions of hereditary hemorrhagic telangiectasia. These findings are similar to those in our family, except that our patients do not show spontaneous purpuric lesions.

Whether the association of a positive tourniquet test with hereditary telangiectasia is fortuitous or is indicative of a more fundamental capillary disturbance presents a problem that necessitates a brief analysis of the clinical pathology of capillary hereditary pathies.

Clinical Pathology of Capillary Hereditary Pathies

In considering capillary functions it is important to distinguish three variables: the contraction of the capillaries following injury (contractility response), the resistance of the capillaries to pressure (capillary fragility) and gross deviation in the histologic structure of the capillaries (telangiectasia). It will be seen that although disturbances of these factors most often occur separately, defects frequently coexist.

Contractility response of capillaries following injury. Following an injury to the capillaries, bleeding stops because of a complicated process involving contraction of the capillaries and plugging of the endothelial defect by a platelet thrombus. MacFarlane,³⁵ to whom much of the credit for the modern concepts in this field must be given, believes that the capillary contraction is the more important process. Prolonged bleeding following capillary injury may therefore be due to diminished contractility, or to quantitative or perhaps qualitative alteration of the platelets, or to a combination of these factors.

Clinically, a prolonged bleeding time is seen in such conditions as thrombocytopenic purpura of various etiologies and in conditions with apparently normal platelets but an abnormal contractility response. In pseudohemophilia, the platelet counts are normal, but deficient capillary contractility has been demonstrated by MacFarlane. The earlier concept of pseudohemophilia, as developed by von Willebrand and Jürgens,³ Morawitz and Jürgens² and others, favored a qualitative alteration of platelets with diminished ability to form a thrombus. Serious doubt has been cast on the validity of this concept. Buckman,³⁶ for example, found that a suspension of platelets obtained from a pseudohemophilic patient produced as rapid a coagulation

of hemophilic blood as did the platelets from a healthy person. At present, although the possibility of qualitative platelet alterations is still undecided, the capillary dysfunction in pseudohemophilia is well established. That diminution of platelets alone does not lead to purpura unless accompanied by capillary damage has been experimentally demonstrated. Roskam³⁷ injected gelatin intravenously into dogs and reduced the platelets to extremely low levels with only a slight or no increase in bleeding time. Bedson,¹⁴ using a solution of agar, obtained similar results. If, however, injections of antired-cell serum preceded the lowering of the platelets, purpura resulted. Antired-cell serum, according to Bedson, damages the capillaries.

Prolonged bleeding time in the presence of apparently normal platelets—as indicated by a normal platelet count and coagulation time—is therefore indicative of a deficiency in capillary contractility response. Furthermore, a deficient contractility response may appear only in localized areas. Roskam³⁷ reported a case in which the patient had a bleeding time of three minutes in one ear lobe and one of forty-eight minutes in the other. It is not improbable that some of the cases of hereditary familial epistaxis without other detectable hematologic deviation¹⁵ represent such localized areas of defective contractility response.

Response of capillaries to pressure. The capillary fragility expresses the resistance of the capillaries to pressure. This is best measured by a modern tourniquet test or by the more elaborate suction method.^{16, 38, 39} These fragility tests depend on the integrity of the capillary endothelium. Clinical observations suggest some relation between platelets and maintenance of the capillary resistance to pressure. In the presence of a normal platelet count and coagulation time, however, a positive tourniquet test may be considered to reflect only an abnormal response of the capillaries to pressure.

Increased capillary fragility may be present with or without corresponding involvement of the contractility response. Since capillary fragility is measured by the tourniquet test, a prolonged bleeding time may therefore be seen with or without a positive tourniquet test, and similarly a positive tourniquet test may be seen independently of an increased bleeding time. A decrease in capillary resistance without a disturbance in contractility response was described by Davis^{4, 5} as hereditary familial vascular purpura. A disturbance in contractility response without a change in capillary resistance is seen in certain pseudohemophilic families.

As yet, localized disturbances of capillary resistance have not been described, probably because the tourniquet test, which has been most widely used for testing capillary resistance, is ordinarily performed only on the upper extremities. With the

introduction of suction tests, however, it will become possible to study localized variations. Analysis of capillary contractility response and fragility, together with their occurrence in clinical observations, have therefore shown that they must be considered as independent variables.

Gross deviation of structure of capillaries. Areas of gross deviation of capillary histologic structure are seen in hereditary hemorrhagic telangiectasia as localized, disseminated lesions. The gross pathology and histopathology have already been described.

The usual form of gross deviation, or typical hereditary hemorrhagic telangiectasia, occurs as multiple lesions in various capillary provinces, but localized single lesions of hereditary telangiectasia are sometimes seen. Libman and Ottenberg¹¹ described a family in which a single lesion in the lung occurred as a familial characteristic.

As a rule, the nonaffected areas in this disease show a normal contractility response and fragility, whereas bleeding time after injury to a telangiectasis is considerably prolonged.²² In certain cases, however, gross deviation of the capillaries is combined with more or less developed abnormalities of contractility response or capillary fragility, precisely as defects in contractility response and fragility are associated. Our family and that reported by Davis⁴ show such a combination of hereditary hemorrhagic telangiectasia with abnormal capillary fragility. The sole difference is that Davis's family showed spontaneous ecchymoses, whereas the increased fragility in our cases was not sufficient to lead to purpuric manifestations. The combination of hereditary hemorrhagic telangiectasia with prolonged bleeding time (deficient contractility response) has not yet been reported, but on the basis of this analysis it may be considered possible.

As can be seen from this discussion, definite pure types of capillary dysfunction are sometimes observed. On the other hand, the diagnosis of a clinical picture in any case of hereditary capillary disorder should depend on analysis of the involved pathologic physiology. Such analysis shows the existence of an interrelated system of capillary functions that may be singly or simultaneously involved. This approach precludes the use of tables of differential diagnosis for these disorders in which only rigidly demarcated types are considered. In the various manifestations of acquired capillary dysfunctions, toxins, nutritional deficiencies (vitamin P deficiency), endocrinopathies and so forth play a role as etiologic factors. No clue is available concerning the mechanism by which the hereditary manifestations are brought about.

SUMMARY

A family presenting hereditary hemorrhagic telangiectasia, together with a positive tourniquet

test, is described. An analysis of the pathologic physiology of capillary hereditary disorders is attempted. An abnormal contractility response of a capillary to injury as expressed by a prolonged bleeding time and an abnormal capillary fragility to pressure, as seen by a positive tourniquet test, represent independent variables that may be singly or simultaneously involved.

Pseudohemophilia is characterized by a prolonged bleeding time but a negative tourniquet test, and hereditary purpura simplex by a normal bleeding time but a positive tourniquet test. Combinations of both types exist.

Hereditary hemorrhagic telangiectasia is a localized gross abnormality of capillaries usually not accompanied by any systemic capillary dysfunction. The observed family represents, however, such a combination of localized gross deviation of capillary structure and increased capillary fragility.

The diagnosis of hereditary capillary syndromes should depend on physiologic analysis and not on rigidly demarcated types of disorders.

MEDICAL PROGRESS

ENDOSCOPY*

EDWARD B. BENEDICT, M.D.†

BOSTON

SOMETIMES wonder whether the general practitioner thinks that the endoscopist, peering through narrow tubes, is "learning more and more about less and less," but when I come to review the voluminous literature on the subject, I realize each year more than ever how many interesting branches of medicine and surgery are involved. Undoubtedly the endoscopist sees a large percentage of the most interesting problem cases in the hospital. Through bronchoscopy and esophagoscopy he is constantly in touch with the new and ever-widening field of thoracic surgery. When he uses the gastroscope, he is endeavoring to confirm or establish gastric diagnoses that might otherwise be obscure or unattainable. Last, but not least, by the use of the peritoneoscope he is differentiating many difficult abdominal problems and establishing a positive diagnosis by biopsy. A review of the literature may help the clinician in deciding when to call the endoscopist in consultation.

ANESTHESIA

There have been a number of verbal reports regarding the toxicity of pontocaine as a topical anesthetic during endoscopy. In last year's progress report¹ a nonfatal reaction was reported. Hansen and Stealy² report a sudden death following the use of pontocaine as a gargle anesthetic. The patient was a man of fifty-four who had received 1½ gr. of pentobarbital sodium orally one hour before, and ¼ gr. of morphine sulfate fifteen minutes before the operation. While gargling 1 dram of 2 per cent pontocaine, he suddenly collapsed. Respiration ceased, cyanosis developed and there was a general-

ized convulsion, followed by several more convulsions during the next hour. In spite of artificial respiration and the administration of luminal sodium, adrenalin, coramine and oxygen, death ensued one hour and a quarter after the collapse. A post-mortem examination revealed a carcinoma of the esophagus with extensive metastases to the liver, but no organic reason for the sudden death could be demonstrated. Because of the manner in which death occurred, and the absence of any other demonstrable cause, it can be concluded only that death was due to an anaphylactic reaction to the pontocaine gargle.

In the clinic at the Massachusetts General Hospital a 4 per cent cocaine for all peroral endoscopies is being used. No reaction to 5 per cent Larocaine Hydrochloride has been known to occur but at the present time this drug cannot be obtained.

In an editorial on modern anesthesia, Lahey³ states that the anesthetist should recognize the importance of keeping the tracheobronchial tree free of secretions and other fluid, and should be prepared and able to remove these secretions before, during and after operation; in other words, he should be familiar with the technic of bronchoscopy and should be able to recognize when this procedure is indicated.

BRONCHOSCOPY

Anatomy. Jackson and Huber⁴ have studied the anatomy of the bronchial tree and lungs with reference to the branching into lobar segmental bronchi and the relation of each lobar and segmental bronchus to its corresponding portion of lung. A nomenclature has been proposed that is quite similar to that suggested by Adams and Davenport.⁵

*From the Massachusetts General Hospital.

†Instructor in surgery, Harvard Medical School; associate visiting surgeon, Massachusetts General Hospital.

Diverticulum of the bronchus. Diverticulum of the bronchus is exceedingly rare. Arce⁶ reports an interesting case that was well demonstrated by bronchography.

Bronchiectasis. Goodale⁷ reports 75 cases of bronchiectasis that were studied to evaluate the importance of surgical treatment of the sinuses. The best results were obtained from lobectomy in cases in which there was no complicating sinusitis. Untreated sinusitis was a distinct hindrance to recovery from the thoracic infection. Likewise, in cases in which the sinuses were operated on but lobectomy was not done, the result was poor. When both adequate operation on the sinuses and lobectomy can be performed, the results are so much better that these two procedures are indicated in all suitable cases. That Goodale's cases were hard to classify may be considered evidence that each patient must be considered separately.

In reporting on 76 patients surgically treated for bronchiectasis, Bradshaw and O'Neill⁸ mention that more and more patients with bilateral disease are being subjected to bilateral lobectomy, with considerable success (Elosser, Lewis, Overholt, Bradshaw and Chodoff, Blades and Graham). Several patients have had three and a part of a fourth lobe removed successfully. The operative mortality in this group of patients is, of course, much higher than that in the unilobar group.

DeBakey and Ochsner⁹ have also written on the surgical treatment of bronchiectasis, calling particular attention to Churchill's¹⁰ recently reported series of 125 cases in which lobectomy was performed with a mortality of only 2.4 per cent. The operative mortality is lowest with children and increases with age. The authors use bronchoscopic aspiration following the operation. The decreased postoperative morbidity resulting from the removal of viscid mucopurulent secretions by this means has convincingly demonstrated its value.

Blades and Dugan¹¹ have demonstrated that, following atypical pneumonia, iodized oil bronchograms occasionally give the erroneous impression of a true bronchiectasis. According to them, if one is aware that atypical pneumonia is capable of producing temporary dilatation of the bronchi, an early or dry bronchiectasis can for a time be considered a pseudobronchiectasis. Progression of symptoms and repeated demonstration of the bronchial dilatation soon establish the correct diagnosis. Failure to consider the possibility of pseudobronchiectasis may result in unnecessary resection of lung tissue.

Vinson,¹² in a discussion of the management of chronic suppurative pulmonary disease, states his belief that any patient with suppuration should have at least one bronchoscopic examination to determine the exact location and distribution of the area of infection. When bronchial stricture is present, adequate drainage can be often provided by bronchoscopic methods, with beneficial or cura-

tive results. Insufflation of powdered sulfanilamide through the bronchus has been of benefit in patients with chronic suppuration. My own experience indicates that sulfadiazine by mouth is equally effective.

Clerf¹³ believes that although bronchiectasis can be cured by conservative measures, this can be considered only if the cases are observed early, before the bronchial mucosa or bronchial wall has been damaged by the infective process. Excellent results have been obtained in patients with minimal bronchiectasis secondary to aspirated foreign bodies. Following removal of the foreign body and repeated bronchoscopic aspiration of secretions, definite regression of the bronchial dilatation has been observed. Too often, however, the diagnosis is not made sufficiently early to permit such a plan of treatment. Patients commonly present themselves with well-defined bronchiectasis involving one or more pulmonary lobes or both lungs. Clerf calls attention to the fact that bronchiectasis is a common chronic pulmonary disease, being oftener observed than is pulmonary tuberculosis. Surgical extirpation of the diseased lung tissue effects a cure. All other methods of therapy are only palliative. He lays considerable stress on the importance of bronchoscopy as an aid in the prevention of bronchiectasis through the removal of bronchial obstruction. Bronchoscopic aspiration of secretions from infected areas aids patients who are too old for surgery or have bilateral lesions that render surgical treatment impractical.

In discussing the sulfonamides in relation to bronchial secretion, Norris¹⁴ states that the general effect of sulfonamide compounds is favorable, particularly when combined with bronchoscopic aspiration. He writes as follows:

We have tentatively preferred the oral method of administration because of comfort and convenience from the patient's standpoint and because its use presumably allows a much more diffuse, uniform and prolonged action than can be obtained by instillation.

The persistence of sputum in bronchiectasis are due to it has appeared to us that it attacked by combining drainage and prevents infection in a rather intensive course with specific antibacterial therapy. This means, in most cases, hospitalization for a period of from seven to ten days....

The concentration of sulfadiazine in bronchial secretion during oral administration is approximately 60 per cent of the blood level. This ratio is apparently not materially affected by the extent of bronchial disease or the amount of expectoration.

After intratracheal or intrabronchial instillation of 5 per cent aqueous suspension of microcrystalline sulfathiazole, significant concentrations persist in the bronchial secretion for twenty-four to forty-eight hours. The concentrations for twenty-four to forty-eight hours. The concentrations are larger, as would be expected, in cases in which there is but little expectoration.

Elimination of 2.5 per cent aqueous solution of sulfathiazole by expectoration.

Combined sulfonamide and bronchoscopic treatment of acquired bronchiectasis resulted in a con-

siderable reduction in daily sputum volume, with favorable alterations in the bacterial flora.

The plan of treatment described should prove of definite value as a preliminary to lobectomy or pneumonectomy for suppurative disease. It is probably worthy of trial in cases of well established nonsurgical bronchiectasis.

Dowling and Lepper¹⁶ have studied the toxic reactions following the use of sulfapyridine, sulfathiazole and sulfadiazine, and conclude that the optimal therapy for most infectious diseases at the present time involves the use of sulfadiazine, in low doses whenever possible but in high doses when necessary, provided there are careful regulation of fluid intake and output and frequent blood counts and urinalyses, combined with close observation of the patient.

Acute tracheobronchitis with edema. Baum¹⁷ reports that acute laryngotracheobronchitis often produces death by inflammatory edema of the subglottic tissues. Concentrated plasma is effective in reducing this edema, which it accomplishes by its high concentration and resultant osmotic action. Such action withdraws fluid from the tissues into the blood stream. It is in no way curative for the infection.

Schmidt¹⁸ calls attention to the importance of benign nontuberculous bronchial stenosis, which may develop secondary to chronic bronchial infection such as that seen in cases of chronic asthmatic bronchitis. Secondary and tertiary bronchi are principally involved, and occasionally primary bronchi. The syndrome of benign nontuberculous bronchial stenosis is a definite one. There is usually a history of antecedent pneumonia, severe tracheobronchitis or repeated seizures of asthmatic bronchitis. After variable periods, recurrent bouts of chills, fever and general malaise develop. The period of fever is usually preceded by an irritating nonproductive cough. The temperature may reach 102 to 103°F., the elevation persisting for two to seven days, at the end of which time variable amounts of purulent secretion are coughed up. This relieves the symptoms. At times the sputum is blood tinged. Bronchoscopy is the only clinical method of determining whether benign bronchial stenosis exists, and it is the only way by which such a lesion can be satisfactorily treated. In one of the cases reported, a bronchogram showed bronchiectasis of the left lower lobe in a patient forty-seven years old. Fifteen months later it had cleared up entirely so that bronchography disclosed no abnormality. In 15 of the 25 cases, bronchial stenosis was secondary to asthma or asthmatic bronchitis. In a certain number of cases the stenosis recurs and it is necessary to repeat bronchoscopic dilatation.

Astmatoid respiration. Friedberg¹⁹ has discussed bronchoscopy with relation to astmatoid respiration. In 8 of his cases there was noisy breathing or wheezing, and in some of them there was a misleading familial history. A number of the cases were due to foreign bodies in the bronchus, whereas

others were due to large amounts of secretion, to bronchial stenosis or to tuberculosis. Friedberg concludes as follows:

Altered respiration of an astmatoid type may result from a variety of clinical conditions which produce changes in the caliber of the tracheobronchial lumen.

Pathologic narrowing of the bronchial lumen, coupled with physiologic shortening and contraction of the bronchi, probably combine to produce an abnormal vibration of the outgoing air during expiration. The resultant sound is often wheezing in character.

Illustrative cases indicate the diagnostic and therapeutic value of bronchoscopy in simulated asthmatic breathing.

Endoscopic investigation is warranted in any case of atypical bronchial asthma which does not respond readily to diagnosis and therapy.

Foreign bodies. Holinger²⁰ reports 5 cases in which confections caused severe obstruction to the airway in children. He calls particular attention to the danger of aspiration of candy or gum in children during rapid respiration. A positive history with physical findings of laryngeal, tracheal or bronchial obstruction establishes the diagnosis.

Bronchial obstruction. Having recently had 2 patients in whom aneurysm of the descending aorta was causing complete obstruction of the left main bronchus with atelectasis of the left lung, I think it is worth while to call attention to the x-ray diagnosis of such lesions by angiocardiology as discussed by Steinberg, Grishman and Sussman.²¹ Aortic aneurysm as a cause of bronchial obstruction is rare, but should naturally be recognized before bronchoscopy is undertaken. Bronchoscopy in aneurysm may be a harmful procedure, and biopsy of the obstructing lesion is almost certain to prove fatal.

Importance of the cough reflex. The importance of preserving the cough reflex in all diseases of the lung cannot be overemphasized. The cough is the "watchdog of the lung" and enables the patient to raise secretions that if left stagnant are definitely harmful. Many physicians, however, unnecessarily order cough medicines that seem to abolish the cough reflex. Occasionally, of course, sedation is necessary to abolish pain. In this connection Johnson²² discusses postoperative pain following total pneumonectomy. He writes as follows:

One's natural impulse is to give patients sufficient morphine to relieve the pain. However, this incurs the danger of diminishing the cough reflex to such an extent that secretions accumulate in the tracheobronchial tree. In one instance, this resulted in atelectasis of the right upper lobe after a left total pneumonectomy. Such a complication may be overcome only by the most energetic treatment.

If, on the other hand, one avoids sedation too long, the patient's life may actually be threatened as a consequence. In at least one patient, the sedation was held off too long for fear of diminishing the cough reflex. Because of pain, the patient began taking shallow rapid respirations. He allowed secretions to accumulate in his tracheobronchial tree to avoid the pain of coughing. Because of these two factors he developed an anoxia and from it went into shock. When a large dose of morphine was given, the pain was sufficiently relieved to allow the patient to cough up the secretion and take deep, even respirations. Having overcome the anoxia, the patient rapidly recovered from the shock with the aid of intravenous fluids.

It has been found therefore that one must proceed carefully along the middle road between too much morphine and too little morphine, either extreme having potentially fatal complications. However, even with the most careful attention, it may often be impossible to reach a stage of sedation which will relieve the patient's pain adequately, and still not depress his cough reflex and respiratory rate to a dangerous degree.

Trauma. Foss and New²³ report a case of traumatic stenosis of the larynx in which the normal lumen of the larynx or upper portion of the trachea was occluded by scar tissue. This condition was treated by a new type of obturator constructed of veronite. Among the advantages of this method are that the device can be worn with comfort, that there is no formation of granulation tissue within the larynx, that there is no discharge and consequently no odor and, that the obturator may be cleaned as an office procedure.

Adenoma. Anderson²⁴ reports a case of so-called "adenoma" with metastases to the liver. The bronchial tumor alone would have been considered benign, but on the finding of metastases in the liver was diagnosed as malignant. In view of this case the author believes that the principle of treatment of bronchial adenoma should be the same as that of malignant tumor. There are undoubtedly borderline cases, but, as pointed out in last year's review¹ the term "malignant adenoma" seems to be somewhat of a contradiction in terms. Mulligan and Harper,²⁵ however, have also called attention to low-growing tumors of the bronchus originally considered to be benign adenomas but shown by later biopsies to be adenocarcinomas. Such tumors must be watched carefully. Lobectomy or pneumonectomy may be indicated in these cases, not only because of the remote possibility of histologic change to malignancy but also because of irreparable lung damage or the existence of a large extrabronchial portion of the tumor.

Carcinoma. Cohen²⁶ reports an interesting case of obstructing emphysema and atelectasis in the same lung resulting from bronchogenic carcinoma. The tumor was so situated in the main bronchus as to occlude completely the orifices of the bronchi of the upper and middle lobes; simultaneously, it caused a check-valve type of obstruction of the bronchus of the lower lobe.

Mulligan and Harper,²⁵ in a detailed study of the morphology of primary carcinoma of the human lung, have discussed the pathologic anatomy in 45 cases. In 3 cases primary carcinoma was found in both lungs, which seems quite remarkable.

Robertson²⁷ reports that carcinoma of the lung ranks in frequency second only to carcinoma of the stomach, the death rate from this condition in Scotland having increased from 437 per 100,000 in 1935 to 559 in 1940. In the 52 cases reported, 37 patients were males and 15 were females.

Further evidence of the importance of bronchogenic carcinoma is contained in an article by Overholt,²⁸ where it is stated that cancer of the lung

is one of the most serious diseases of the chest in patients within the age period from forty to sixty-five years, particularly in men; that many patients seek help at a time when the lesion is still confined to the lung; that symptoms and signs are either lacking or misleading in the early stages; that the earliest lesions in almost every case produce some telltale shadow on the x-ray film; and finally that the diagnoses may be clinched in two ways — first, the majority of lesions are visible bronchoscopically and are accessible for biopsy and, second, when the suspicion cannot be verified in this way, it is possible to explore the chest safely by surgical means, settle the diagnosis and if necessary carry out curative treatment.

Fetter²⁹ also comments on the increase in frequency of primary carcinoma of the lung as shown in recent reviews. It appears that 10 per cent of all cancers start in the lung and that it is now the second most frequent site of origin of primary malignancy, the stomach being involved more than any other organ. In the United States about 15,000 people die from bronchogenic carcinoma every year. Many factors have been considered as possible causes of the disease: the influenza epidemic of 1918 (metaplasia of the bronchial mucosa has been found in patients dying of influenza); inhalation of irritating fumes, such as the exhaust from automobiles, the fumes from tarred roads or tobacco smoke (the fact that carcinoma of the lung is at least four times as frequent in men as in women has been cited in support of the tobacco-smoke theory); silicosis; tuberculosis; and other nonspecific lung infections, such as bronchiectasis and lung abscess. The author emphasizes the importance of early bronchoscopy in suspected cases and the fact that thoracotomies should be done only by those trained in thoracic surgery.

In the early diagnosis of carcinoma of the lung, Gower³⁰ points out the value of sputum examination by the sinear method of Dudgeon. The sputum should be coughed up the first thing in the morning so that there will be no contamination with food particles. Preservatives or disinfectants must not be added, and the specimen should be examined as soon as possible after collection. Specimens collected at bronchoscopy or coughed up shortly afterward are suitable for examination. Dudgeon advised that the sputum be poured onto an unglazed porcelain tile to concentrate it, but Gower found that by examining it in a large Petri dish on a black background it was easier to pick out portions for examination. Blood-streaked fragments or the relatively solid portions are picked out with a platinum loop or scalpel and are spread thinly on a slide. Several slides are prepared from each sputum. They are fixed by immersing them at once in a bath of Schaudinn's solution, leaving them there for twenty minutes and washing them for two minutes in 70 per cent alcohol containing a trace of iodine, to

remove the excess of mercury bichloride, and then in distilled water. The slides are stained with Mayer's hemalum for one and a half to two minutes, blued in tap water, counterstained with eosin for two minutes, dehydrated and mounted in Canada balsam. They are then examined with the low power of the microscope, and any suspected group of cells is submitted to a higher magnification. When the clinical evidence is strongly in favor of carcinoma, several specimens of sputum should be examined before a negative report is made. A negative report does not exclude malignant disease. Gowar used this method in 93 cases of suspected neoplasm of the lung. In 64 per cent of the cases he succeeded in demonstrating malignant cells. The cells were found not only in advanced cases but also in a significant proportion of those in which the growth was still operable. The test is of value in establishing malignancy when other methods of investigation, including bronchoscopy, have failed, when it is desired to explore the chest, when the patient is too ill to be submitted to other methods of investigation and when the growth is masked by secondary inflammatory changes in the lung. It is urged that the test be more widely employed and that aspiration biopsy be reserved for cases giving repeatedly negative sputum tests, not being used when surgical removal of the growth is envisaged.

Field and Quilliam³¹ report the case of a four-and-a-half-year-old girl with primary bronchial carcinoma. She had always been in good health until eleven days before admission, when she developed an unproductive cough with periods of apnea. Physical examination revealed a cyanotic, dyspneic child and the presence of pleural effusion on the right, which steadily increased in spite of repeated thoracenteses. Examination of withdrawn fluid revealed many mesothelial cells suggestive of malignancy. On thoracoscopy many neoplastic nodules over the parietal pleura were seen, and histologic examination showed them to be infiltrating anaplastic carcinoma of the bronchial type. The patient expired two months after admission with evidence of metastases to the supraclavicular lymph nodes and also extension of the tumor to the chest wall. Autopsy revealed a carcinoma of the bronchus with extensive pleural involvement and metastases to the bronchial, mediastinal, right supraclavicular and axillary and celiac-plexus lymph nodes.

Metastatic pulmonary malignancy. Brezina and Lindskog³² report the case of a sixty-five-year-old woman who was submitted to right total pneumonectomy for a discrete tumor of the right upper lobe. A subtotal hysterectomy and bilateral salpingo-oophorectomy had been performed thirteen years previously for vaginal bleeding and a gross diagnosis of uterine carcinoma had been made. Recent cough and blood-tinged sputum caused the patient to seek medical help. She recovered from the operative procedure. The removed lung showed

a solitary metastasis of uterine adenocarcinoma. On examination five months later the patient was in good general condition, with no evidence of recurrence.

King and Castleman³³ made an autopsy study of bronchial involvement in metastatic pulmonary malignancy. They report as follows:

Necropsics performed at the Massachusetts General Hospital over a ten-year period on patients with metastatic pulmonary neoplasm were investigated in order to discover the incidence of those in whom actual invasion of the bronchus occurred. In 109 cases of pulmonary metastatic tumor 18.3 per cent showed bronchial invasion. In addition to these, 3 patients with malignant lymphoma showed bronchial invasion. It is believed that the incidence would have been much higher if especial attention were paid to the gross examination of the complete bronchial tree and if more sections were taken for microscopic study. Detailed analysis was made in 20 cases in which infiltration of the bronchial tree was found and the following observations were made: The neoplasm in 14 was carcinoma; in 6, sarcoma. Four patients (20 per cent) raised blood-streaked sputum. Nine patients (40 per cent) had no pulmonary symptoms.

Conclusions. Metastatic pulmonary neoplasm may simulate a primary tumor. In a patient suspected of having pulmonary neoplasm, the raising of blood-streaked sputum cannot be considered as pathognomonic of a primary tumor. But the raising of blood in a case of metastatic pulmonary neoplasm is rare. In the present study, it occurred in only 4 out of 109 cases.

Tuberculosis. After deploring the fact that many bronchoscopists are not primarily interested in bronchoscopy or diseases of the chest, Lloyd and Budetti³⁴ go on to discuss bronchoscopy in pulmonary tuberculosis. They believe that the lesion in the bronchus is the same as that in the lung, and that the healing of the intrabronchial ulcer is conditioned on the development of a negative sputum, in which event the patient shows progressive improvement in the bronchus paralleling that in the lung. In view of the underlying pathology, they say, it is difficult to see how either cauterization of ulcers or dilatation of strictures can be of much value. They are opposed to dilatation because they have never seen a permanent increase in lumen by this procedure and are afraid of possible recurrence of pain, hemoptysis and even tubercle bacilli.

Warcalde³⁵ made autopsy studies of 3 cases in which there was an association of pulmonary tuberculosis and primary cancer of the bronchus. These cases proved that tuberculosis and cancer of the lung may coexist, and the author is inclined to think that this association is more frequent than is generally believed. In 2 of his cases, cancer had developed in a bronchus that had been chronically damaged by material eliminated from an old tuberculous cavity. In the third case, there was malignant degeneration of an old tuberculous cavity that had been partially epithelialized. These cases, as well as others cited from the literature, prove that chronic tuberculosis may bring about changes in the tissues from which cancer may develop. Nevertheless, tuberculosis cannot be considered a precancerous disease, nor is it true, as Ewing claimed,

that chronic tuberculosis is the chief cause of cancer of the lung. Warcalde goes on to say that there is no doubt that cancer may bring about exacerbation of old tuberculous lesions of the lung. This, too, was seen in these cases. Paradoxically, tuberculous lesions may disappear in the course of cancer. In one of these cases tuberculous tissue had been destroyed by the advancing cancer, and he cites a case described by Frommel in which no tuberculous tissue was found in the lungs of a patient dead of bronchial cancer who during life had repeatedly shown tubercle bacilli in the sputum. The cancer had destroyed both normal and tuberculous tissue after having caused exacerbation of the tuberculosis.

Tuttle, O'Brien, Day and Phillips,³⁶ in a study of 92 patients with ulcerobronchial or healed bronchial stenosis, made the following observations:

Thirty-two per cent of this group are dead. Thirty-three per cent are still classified as unstable. Sixty-nine patients had ulcerostenosis when first seen. The ulcerative lesion was treated with 30 per cent silver nitrate. Seventy per cent of the group healed while 30 per cent did not change or become worse. Pneumothorax as a method of controlling the parenchymal processes has been compared with thoracoplasty. Pneumothorax was adequate in only 12 of the 47 instances in which it was used. The incidence of empyema and unexpanded lungs is high (31.9 per cent and 46.7 per cent, respectively). Thoracoplasty has yielded results superior to pneumothorax.

During the past year several articles have appeared on lobectomy and pneumonectomy for tuberculosis. Churchill and Klopstock,³⁷ report 6 cases of pulmonary tuberculosis, 3 of which provided orthodox indications for resection of the lesion by lobectomy. Three others presented the usual indications for thoracoplasty but lobectomy was performed by election. Healing per primam resulted in all cases. Lobectomy provides a more selective and immediate method of eradicating certain lesions of tuberculosis than does collapse therapy. It may be used subsequent to artificial pneumothorax, thereby restoring to that procedure the reputation of finesse that it should enjoy. A method of treatment that combines conservation of lung function with immediate conversion of the sputum and a shortening of the span of treatment cannot be dismissed until its scope has been more fully explored. All patients were subjected to bronchoscopy preoperatively to rule out

ulceration in the trachea and sometimes in the bronchus

(To be concluded)

CASE 30211

PRESENTATION OF CASE

A fifty-one-year-old machinist entered the hospital because of shortness of breath and productive cough.

The patient was in excellent health until one month before admission, when he developed a heavy cold characterized by malaise and cough, the latter usually occurring after returning from work in the evening and being relieved by the raising of a plug of greenish sputum. He felt so poorly that he stayed out of work for three or four days, during which time there was no change in his symptoms. He then returned to work but was weak and short of breath. He collapsed and was taken home, where he rested for ten days. He was then admitted to a community hospital, where x-ray studies were done and about 1500 cc. of fluid was removed from his chest, with considerable relief. He was discharged at the end of eight days under the care of a roentgenologist, who gave him "high-frequency" x-ray treatment every other day for a few days, without relief. The treatment was stopped and he became progressively more dyspneic. There was no chest pain, hemoptysis or known weight loss. For two months before the onset of his illness he had been constipated and had noted a decrease in the caliber of his stools. The abdomen became more protuberant and he experienced occasional transient crampy pain in the abdomen. He had no nausea, vomiting, loss of appetite or clay-colored or tarry stools.

Physical examination showed a well-developed, well-nourished, dyspneic man. The neck was "swollen" on both sides. The heart was not remarkable. There was dullness over the entire left chest, with decreased breath sounds, bronchial breathing and absent tactile fremitus. The abdomen was distended, with a fluid wave and shifting dullness.

The blood pressure was 130 systolic, 80 diastolic. The temperature was 99°F., the pulse 100, and the respirations 25.

Examination of the blood showed a red-cell count of 3,200,000, with 90 per cent hemoglobin. The white-cell count was 11,500, with 92 per cent neutrophils, 6 per cent lymphocytes and 2 per cent mono-

cytes. The urine was normal. A blood Hinton test was negative.

X-ray examination revealed a large amount of fluid in the left pleural cavity, which compressed the left lung and displaced the heart and mediastinum to the right (Fig. 1). There appeared to be widening of the superior portion of the mediastinum on the right. The right lung field was fairly clear, with some increase in the markings. A small amount of fluid was seen in the right costophrenic angle. A barium enema was unsatisfactory because of inadequate preparation, but no abnormality of the colon could be demonstrated. The liver was somewhat enlarged. Thoracentesis in the left seventh interspace yielded 2400 cc. of watery, red fluid with a specific gravity of 1.011. A culture was negative, and no tumor cells were seen in the sediment. Following this procedure the patient improved considerably but temporarily. A second thoracentesis two days later yielded 750 cc. of similar fluid, but the dyspnea increased and he died on the fourth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. REED HARWOOD: I take it that this patient did not have a cold. There is no mention of sore throat or coryza. I also presume that the radiologist in the outside hospital was able to see something after the chest tap that gave him an idea concerning the diagnosis. Our x-ray films are not definite enough to justify a diagnosis.

It is not clear from the history when the swelling of the abdomen took place.

The description of the cervical swelling could mean anything or nothing. Did it mean masses, was this actual edema of the neck or was it simply due to distended jugular veins?

DR. FRANK WHELOCK: The swelling was at the base of the neck in the midline, extending down to the shoulder. It was fairly firm, but not a mass; just a swollen neck.

DR. HARWOOD: Was the bronchial breathing heard throughout the whole chest or simply near the upper level of the fluid?

DR. WHELOCK: It was above the level of the fluid.

DR. HARWOOD: There must have been absent breath sounds low on the left side.

This man died soon after admission and presumably never had a bowel movement after entrance to the hospital, but with a story of crampy abdominal pain and decrease in the caliber of the stools, a test for occult blood in the stool would have been important.

DR. BENJAMIN CASTLEMAN: Blood examination at the outside hospital showed a red-cell count of 4,100,000, with 80 per cent hemoglobin.

DR. HARWOOD: We might see the x-ray films at this point.

*On leave of absence

DR. LAURENCE L. ROBBINS: As is fairly evident, there is a large amount of fluid in the left pleural cavity displacing the heart and mediastinum to the right. There is a small amount of fluid in the right pleural cavity. I cannot tell much about the left lung. These films are suspicious of some disease within the lung, but it is indefinite on account of the fluid. A fairly important observation is the appearance of the right side of the superior mediastinum, which is large and somewhat lobulated in out-

the lung was pushed anteriorly. There is no evidence of the mass extending up into the neck. Everything has been pushed over to the right.

DR. HARWOOD: Do you think the tumor alone has produced this angulation?

DR. ROBBINS: I think that that is sufficient reason to explain it.

DR. HARWOOD: The outstanding feature of this case is the rapidity with which the patient died. There is little in the way of symptoms on which

FIGURE 1. Roentgenogram of Chest.

line. The right lung is probably clear. It has a peculiar appearance, which is probably due to compression from the displaced mediastinum.

On taking a quick look at the films of the barium enema, I do not believe there is much information to be obtained from them. The patient was not particularly well prepared.

DR. HARWOOD: This shadow here is perhaps the mediastinal tumor.

DR. ROBBINS: I do not believe that we have any way of knowing. Perhaps the patient was in a horizontal position for some time, and as the fluid accumulated in the posterior portion of the chest,

to make a diagnosis until just a month before his death. I believe that he died of a malignant neoplastic disease, but I admit that I have little idea of what form of malignant disease it was.

It seems highly unlikely that this could have been an infection. With bloody pleural fluid and ascites, one might consider a generalized tuberculous infection. The patient, however, had no fever, and the disease was much too rapid in its downhill course.

The malignant diseases that we should consider are carcinoma, fibrosarcoma and some type of lymphoma. Before seeing the x-ray films, I did

not realize that the mediastinal lymph nodes were as enlarged as they seem to be on this x-ray film, and I considered carcinoma as the likeliest diagnosis. The question is, Where did it arise? We have one hint in the abdominal symptoms that he had. Did he have carcinoma of the colon? I am inclined to think not. I may be reasoning erroneously when I say that carcinoma of the colon is usually slowly growing, with metastases manifesting themselves late. I am going to rule it out.

Did he have carcinoma of the liver? The liver was enlarged, and that is the only single finding we have to implicate the liver. There were no abdominal masses and no jaundice. I am going to exclude the liver as the possible site of the tumor.

Did he have carcinoma of the stomach? The outstanding complaint might have been due to carcinoma high in the fundus. Carcinoma of the fundus occasionally goes unsuspected until metastases occur. He could easily have had metastases both to the peritoneum and to the lung and pleura.

Carcinoma of the lung must be considered, of course. He could have had a small carcinoma in a silent area of the lung, arising from a small bronchus so that, while the tumor grew, it did not invade a large bronchus to produce cough, hemoptysis and wheezing; then, as it approached the pleura, it might have produced pleural effusion and also metastases, both to the mediastinal lymph nodes and to the peritoneum. That is unusual, but I have an idea that this case is unusual, which is why it was presented.

Another possibility is that he had lymphoma—a generalized lymphomatous disease—with the most obvious manifestations in the mediastinal lymph nodes. The first real symptom might have been the cough, which suggests that the mediastinal tumor was pressing on the left main bronchus and that the mediastinal tumor grew to considerable size before producing definite symptoms.

I am at a loss to decide which of these attractive possibilities to choose, but I am going to place as my first bet lymphosarcoma of the mediastinal lymph nodes, pleura and peritoneum, and as the second bet, carcinoma of the lung, with metastases to the pleura and peritoneum. There is one possibility that I might mention, although I have no great confidence in it. With the mediastinum so involved, the inferior as well as the superior vena cava might have been pressed on by the tumor, producing, as it could easily, enlargement of the liver and ascites. Against that possibility is the fact that he had no peripheral edema.

DR. JOSEPH C. AUB: Could the patient have died from replacement of the mediastinum to the left following the removal of the fluid? What does the mediastinal syndrome come from?

DR. ROBBINS: I think that it is due to pressure of the tumor rather than to that of the fluid itself. I do not recall having seen an upper mediastinal syndrome produced by fluid.

DR. AUB: I mean that death occurred because of replacement of the mediastinum to normal after the removal of the fluid. Why does it happen? It does.

DR. JACOB LERMAN: Death under those circumstances would be extremely rapid. This man lived for practically two days.

DR. CASTLEMAN: One interesting point is that, while the patient was in the hospital, the left arm became swollen quite suddenly and markedly. Dr. Harwood, have you any further impression?

DR. HARWOOD: The fact does not seem to have any diagnostic importance. We know that he had enlarged mediastinal lymph nodes. Swelling of either arm, the face or the neck can occur at any time with an expanding mediastinal lesion.

CLINICAL DIAGNOSIS

Mediastinal tumor, with extension to lung.

DR. HARWOOD'S DIAGNOSIS

Lymphosarcoma of mediastinal lymph nodes, pleura and peritoneum, with metastases?

Bronchiogenic carcinoma, with metastases to mediastinal lymph nodes, pleura and peritoneum?

ANATOMICAL DIAGNOSES

Oat-cell carcinoma of left lung, with extension to trachea, pleura and pericardium, with compression and thrombosis of left subclavian vein and with metastases to the vertebrae.

Hemothorax, bilateral.

Pulmonary atelectasis, left.

Bronchopneumonia, right lower lobe.

Peripheral edema of arms.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The autopsy on this man showed a large nodular mediastinal mass, which was believed to be involved lymph nodes. The mass extended upward about 3 cm. into the suprasternal notch, inferiorly to cover the upper third of the external surface of the pericardium and then to the left to involve the pleura of the left lung all along the hilus. When we cut across the mass we could see that it surrounded the aorta, the left subclavian vein and the right side of the superior vena cava. All the structures in that region were compressed but apparently not infiltrated by the tumor. The left subclavian vein was thrombosed. Because the superior vena cava was merely compressed rather than infiltrated, we thought that the best diagnosis was some form of malignant lymphoma, since carcinoma is usually infiltrative.

On opening the trachea and bronchi we found that there was extensive involvement of the left main bronchus with tumor, but the lumen was still patent. The mediastinal nodes surrounding the trachea

had penetrated the trachea in one place to form an intrinsic mucosal plaque of tumor 1 cm. long and 3 mm. wide. It is interesting that in so doing the tumor, as is usual, surrounded the cartilaginous plates and not destroyed them. The tumor had extended into the lung parenchyma.

On microscopic examination the tumor proved to be an oat-cell carcinoma of the lung. The only other metastases found, in addition to the mediastinal lymph nodes, were in the vertebrae, which were almost completely replaced by tumor, and one certainly should have expected severe myelophthisis anemia.

DR. HELEN PITTMAN: Did he have ascites?

DR. CASTLEMAN: No.

CASE 30212

PRESENTATION OF CASE

A sixty-six-year-old housewife entered the hospital because of severe pain in the right leg.

The patient was known to have been hypertensive for many years. For several months before entry she had "palpitation" and had been given 3 gr. of quinidine four times daily. She had been in fairly good health for the preceding two or three weeks and was able to carry on with the usual housework. Early one evening, about twenty-two hours before admission, she was suddenly seized with an intense, substernal pain in the chest, which radiated to the right midback and was aggravated by inspiration. She felt that she could not breathe. The pain was followed almost immediately by intense pain in the right leg, extending from the hip to the foot. The leg felt completely numb and she could not move it. She was seen by her physician who found her in shock — cold and clammy. The pulse was 120 and regular. The blood pressure, which had been around 250 systolic, 190 diastolic, was 200 systolic, 110 diastolic. There was no fever. After the onset of pain in the leg, the pain in the chest practically disappeared and she was able to breathe without difficulty. This, however, may have been due to the fact that the former was so severe that the latter was ignored. She was given $\frac{1}{2}$ gr. of morphine through the night and the next morning, without relief. She perspired considerably, but voided little urine. She had had "virus pneumonia" three or four months prior to admission, followed by a chronic productive cough and by general sinus infection.

Physical examination showed a well-developed, well-nourished, sallow patient who appeared to be critically ill and complained bitterly of pain in the right leg. The leg was swollen, cold, "anesthetic and paretic," with mild grayish cyanosis involving the entire extremity; no arterial pulsation could be felt. She could not wiggle her toes. The heart was enlarged, the left border of cardiac dullness being 10 cm. to the left of the midline in the fifth space.

The sounds were regular. A rough, distant, systolic murmur, loudest at the apex, was heard by one observer. Examination of the lungs was unsatisfactory. The abdomen was negative.

The blood pressure was 110 systolic, 60 diastolic, in the right arm, and 115 systolic, 60 diastolic, in the left. The pulse was 92. The temperature and respirations were normal.

The patient was given $\frac{1}{4}$ gr. of morphine every three hours and $\frac{1}{2}$ gr. of papaverine every four hours. A lumbar paravertebral novocain injection was performed in the right first, second and third lumbar regions without any objective or subjective change in the leg. About ten hours after admission rectal bleeding was noted. The pulse rose to 110, the respirations were 30, and the blood pressure fell rapidly. There was some bloody sputum, and the patient died a few minutes later.

DIFFERENTIAL DIAGNOSIS

DR. WYMAN RICHARDSON: The story as we are given it here seems to me definite and quite pathognomonic. I know of no condition that produces intense chest pain followed shortly by terrific pain in the leg other than a dissecting aortic aneurysm, and that seems to me the only possible diagnosis in this case.

The heart examination is not particularly specific although there may have been varying murmurs; at least the suggestion here is that the murmur was heard by only one observer and was loud. Physical examination corroborates the diagnosis of dissecting aortic aneurysm.

In regard to other possible diagnoses, I am so sure about this that it looks as if I might be riding to a fall; although I do not see how the diagnosis can be anything else. If one has to make another diagnosis, one must contemplate something that will produce intense chest pain and obstruction to the right iliac artery or some large artery of the leg. If one is considering the possibility of a venous embolus, there might be intense chest pain with a pulmonary embolus. I suppose it is conceivable that one could have a paradoxical embolus to the right iliac artery, but it would have to be a big patent foramen ovale to allow the embolus to get through; and that seems hardly worth considering. The only other thing I can think of is a silent coronary occlusion with a myocardial infarct, followed by a mural thrombus; then a second myocardial infarct, this one not silent, producing severe pain in the chest and at the same time dislodging the previous thrombus and sending it to the iliac artery. This also seems to be an almost impossible coincidence. Otherwise I cannot think of any condition that would produce intense pain in the chest and would occlude the right iliac artery.

Regarding the laboratory findings, I am interested for my own benefit to know — possibly Dr. Castleman does not have this knowledge — whether there

was increased leukocytosis. One would expect that with a dissecting aneurysm, where blood is being disseminated through tissues not used to having a lot of free blood in them, there would be considerable leukocytosis.

DR. BENJAMIN CASTLEMAN: No blood count is recorded.

DR. RICHARDSON: I thought that might be the case.

The other thing I want to speak of is the matter of therapy. Evidently the hope was that a good deal of the difficulty with circulation in the leg was due to secondary spasm; hence, efforts were made to relieve the secondary spasm of the artery. I do not believe that the method employed would have been particularly successful. There is one procedure I can think of — and it has been attempted¹ — that might relieve the whole situation, namely, to open the iliac artery and also to make an opening in the dissecting aneurysm, so that the pressure from the arterial system is relieved, as sometimes happens spontaneously. This may produce a remission, often of considerable duration. We had a case on the ward some years ago in which I took great pride in making a diagnosis of dissecting aneurysm. The patient got well, and subsequently this diagnosis was discarded. I am taking this opportunity to brag about the fact that this patient, who died several years later, did have a dissecting aneurysm that had evidently dissected some years before. In the present case, as I said before, I cannot see how the diagnosis can be anything other than dissecting aortic aneurysm.

There remains one thing to discuss — the manner of the patient's death. As you probably all know, these patients often die of cardiac tamponade, owing to the leakage of blood into the pericardial sac or around the coronary arteries, with pressure on the coronary arteries and a final rupture into the pericardial sac with cardiac tamponade. That seems the likely reason for this patient's death. It ought to be mentioned that such patients sometimes develop anuria due to pressure around the renal arteries, with renal ischemia. Hematuria is not an uncommon finding in these cases.

The pathological findings also might be discussed. There is usually a cystic necrosis of the aorta. I believe that this condition may arise from a purely atheromatous lesion, and there may be reason to doubt whether this patient actually did have cystic disease of the aorta. If, however, one is to bet on chance it is much better to say that there was cystic degeneration of the aorta. I cannot think of any incidental findings that may be found. One might say that in patients of this age it probably is a better procedure to try to think of all the various pathologic lesions that there might have been, because one often finds a great many different lesions occurring in such patients, and I am rather inclined to disagree with Dr. Cabot's dictum, namely, that

one should make one diagnosis fit all the symptoms. In this case, with the symptoms given, I can think of but one diagnosis that fits all the symptoms and that is dissecting aortic aneurysm.

DR. CASTLEMAN: Does anyone want to quiz Dr. Richardson?

A PHYSICIAN: How does he explain the bloody stools?

DR. RICHARDSON: I meant to mention the bloody stools. I do not explain them on the basis of aortic aneurysm. It seems conceivable that there might have been sufficient interference with the arterial supply to the lower rectum, in the same manner that there was interference to the supply of the blood to the leg, so that there was an ischemia or infarct involving the lower bowel.

DR. CHESTER M. JONES: Could you not have interference with the inferior mesenteric vessels, with probably an infarct in the region that they supply?

DR. RICHARDSON: Yes; I thought that might explain it. I do not know why, but I have a hunch that the pathologist will not be able to explain the bloody stools.

CLINICAL DIAGNOSIS

Dissecting aneurysm?

DR. RICHARDSON'S DIAGNOSIS

Dissecting aortic aneurysm.

ANATOMICAL DIAGNOSES

Dissecting aneurysm of aorta, with involvement of the major branches and occlusion of the right common iliac artery.

Pulmonary hemorrhage, bilateral.

Hemothorax, bilateral.

Hemopericardium.

Hemoperitoneum, slight.

Cardiac hypertrophy, hypertensive type.

Early infarction of intestine?

Arteriosclerosis, generalized.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The autopsy on this patient showed what Dr. Richardson predicted. This patient did have an aortic dissection. The physician in charge of this case reasoned the same way, but he was not so sure of his diagnosis. In the first place the hypertension did not remain up, as it does in the majority of cases. In this case the blood pressure had fallen.

DR. RICHARDSON: The blood pressure does not fall in the majority of cases?

DR. CASTLEMAN: In most of the cases that we have had here, the blood pressure has remained elevated.

DR. C. SIDNEY BURWELL: That is true. It is one of the differential points between coronary thrombosis and aortic dissection.

DR. CASTLEMAN: In about 80 per cent of our cases the pressure remained elevated,² and the man in charge of this patient thought that that was one point against dissecting aortic aneurysm. He also thought that the patient should have continued to have at least some pain in the chest, which apparently she did not have after the initial attack.

At autopsy the heart was slightly enlarged and of the hypertensive type. In the arch was the intimal tear, a horizontal one that involved one third of the circumference of the aorta. There was only a slight to moderate amount of arteriosclerosis, but the intimal tear did not arise on an atheromatous plaque—in fact it very rarely, if ever, does. The tear went through the intima and two thirds of the way through the media, dissecting proximally to the annulus of the aortic valve and distally down the whole length of the abdominal aorta, first into the carotid and innominate arteries and then into both renal arteries (Fig. 1). The dissection around the mouths of both renal arterics accounted for the anuria. It extended into the right iliac artery, elevating the intima and producing a complete occlusion. It also dissected into the openings of the celiac axis and the inferior and superior mesenteric vessels. The small bowel was completely filled with blood and showed early gangrene.

The external perforation of the aneurysm was not too clear. We found only 250 cc. of blood in the pericardial cavity, much less than one sees with rupture of the adventitia that produces cardiac tamponade, which was not present. There was also about 200 cc. of blood in each pleural cavity, but here again there was no definite external rupture of the adventitia. Blood was present in the adventitia of the main pulmonary arteries and extended into the lungs so that we found hemorrhage into both lungs, a condition that we have seen twice before. I suppose the patient really died because of the slow oozing of blood throughout all parts of the aorta.

Microscopic examination of the aorta showed medial degeneration.

DR. RICHARDSON: Were the coronary arteries dissected?

DR. CASTLEMAN: No.

DR. RICHARDSON: Do you suppose that the extensive involvement of the leg could have accounted for the drop in blood pressure?

DR. BURWELL: The amount of blood that the patient had lost might have accounted for it.

DR. CASTLEMAN: This case would probably have not been a good one on which to try the iliac-artery

FIGURE 1. Drawing Showing the Extent of the Dissecting Aneurysm.

operation that Dr. Richardson mentioned. The patient was much too sick.

DR. BURWELL: Has that really been done?

DR. CASTLEMAN: Not here, but it has been tried in New York City, as I have already mentioned. The patient died six days after operation.

PENICILLIN

THANKS to the initiative and enterprise of certain pharmaceutical houses and other industrial plants, supplies of penicillin have increased to such a point that the drug is about to be released for more extensive civilian use than has been possible during the past year. Up to this time only a limited quantity has been available for emergency civilian use in connection with the War Production Board through the committee of the National Research Council. Greater amounts are now on hand, allocation will be continued by the War Production Board by an advisory panel representing the National Research Council, the United States Army, Navy, Service and the American Medical Association.

To aid in the proper storage and distribution of penicillin, a list of "depot hospitals" has been prepared by the Office of Civilian Penicillin Distribution of the War Production Board, those selected for New England being designated elsewhere in this issue of the *Journal*. Each hospital will be permitted to purchase a monthly quota, and other hospitals in its vicinity will be allowed to obtain their supplies through this depot.

The responsibility for the intelligent civilian use of this new drug now rests in the hands of practitioners, and they should not fail to realize that the supply is still limited. Penicillin has been proved capable of remarkable therapeutic results; on the other hand, its indiscriminate use in all types of infection will result in a shortage for the treatment of the very type of case in which a cure may be expected.

PHYSICAL MEDICINE

THE gift of \$1,100,000 by Bernard M. Baruch to sponsor the development of teaching and research in physical medicine comes at a particularly opportune time. In the physical rehabilitation of wounded and ill soldiers and sailors and victims of industrial accidents, as well as of the young and old suffering from disabilities of locomotion, physical and occupational therapy is destined to play an important role. Mr. Baruch's interest in physical therapy arose because of his father Dr. Simon Baruch, a prominent hydrologist and a pioneer in this field, and was further stimulated by a desire to aid disabled war veterans. His decision to benefit physical medicine, however, was dependent on the results of a thorough scientific exploration of the subject. To accomplish this a committee under the chairmanship of Dr. Ray Lyman Wilbur and directed by Dr. Frank H. Krusen was formed. Nine subcommittees were also appointed, including those dealing with the subjects of poliomyelitis, occupational therapy, prevention and body mechanics, hydrology and health resorts, clinical and basic research, rehabilitation and teaching. Over four hundred scientists were consulted in the course of a comprehensive three-month survey. The final report, seeking to emulate those famous reports of Mr. Baruch for which he

became known as "Mr. Facts," is a valuable source of information on the multiple aspects of physical medicine.

This report emphasizes the wide scope of physical medicine and its possible application in nearly all fields of medical practice. Physical agents produce striking biologic responses and psychic reactions, which in potency compare favorably with those of drugs and other established therapeutic procedures. In order that these agents may be widely recognized and used the primary step in development is considered the education of teachers and specialists in physical medicine. This is to be accomplished by establishing key centers in selected medical schools where, through basic and clinical research, a background of scientific knowledge will be accumulated. Teachers will be trained in these centers who, in turn, will go to the medical schools of the country to educate future physicians in what are considered to be the important essentials of physical therapy. A supply of specialists will also become available to aid in postwar physical rehabilitation. The center at the College of Physicians and Surgeons, Columbia University, will serve as the chief training center where all phases of physical medicine will be developed and co-ordinated, including electronics, hydrology, climatology, manipulative procedures and occupational therapy. Hydrology and spa therapy will be the major concern of another center, and at the third, the structural mechanics of the body will be studied. An important aspect of this will be a careful scientific analysis of nonmedical, therapeutic procedures and claims by practitioners of osteopathy, chiropractic and naturopathy.

Extensive fundamental studies must be made, and results cannot be expected at once. Scientific data are accumulated only slowly and painstakingly. The wisdom of setting up these centers on a ten-year basis is thus apparent. It is reasonable to expect, however, that proper recognition and an increased use of physical medicine will be achieved in a fairly short time. The full benefits of this million-dollar gift will not be apparent until physical medicine is firmly established on a scientific basis by this preliminary period of research. The future practice of medicine will then be influenced by the widespread instruction of medical students in the procedures of

physical therapy that have proved to be worth while. Provided that the work at the key centers is successfully carried out with the active co-operation of the medical faculties and that the anticipated results are obtained still greater projects, already outlined in the original report of the committee, have been promised similar financial aid. One envisions an important step in the progress of medicine accelerated by Mr. Baruch's perceptive philanthropy.

MASSACHUSETTS MEDICAL SOCIETY

DEATH

WENTWORTH—Mark H. Wentworth, M.D., of Concord died May 15. He was in his sixty-sixth year. Dr. Wentworth received his degree from Harvard Medical School in 1903. He was a member of the Massachusetts Medical Society, the American Medical Association, the Boston Surgical Society and the New England Pediatric Society.

His widow, two daughters and two grandchildren survive.

COMMENT

Diphtheria remained relatively high—twice the seven-year median, although the disease was below the level of the last two months of 1943.

Meningococcal meningitis was at a point almost seven times the seven-year median but was much below the level of March of last year. Nevertheless, the total number of cases for the first three months of this year exceeded that for the corresponding period of last year.

The thirteen cases of salmonella infections represent a new high for March. They were not widely distributed, however, seven of them occurring in one city.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Actinomyces was reported from Palmer, 1, total 1.
Diphtheria was reported from Boston 5, Cambridge, 1, Lawrence, 15, Lowell, 1, Mattapoisett, 1, Methuen, 1, Salem, 1, total, 25.

Dysentery, amebic, was reported from: Fort Devens, 1; total, 1.

Dysentery, bacillary, was reported from: Boston, 2; Worcester (State Hospital), 17; total, 19.

Encephalitis, infectious, was reported from: Braintree, 1; total, 1.

Lymphocytic choriomeningitis was reported from: Springfield, 1; total, 1.

Malaria was reported from: Boston, 1; Camp Edwards, 14; Cushing General Hospital, 7; Fall River, 1; Fort Banks, 11; Fort Devens, 20; Haverhill, 4; Millbury, 1; Milton, 1; Newburyport, 1; Plymouth, 1; U. S. Marine Hospital (Boston), 1; total, 63.

Meningitis, meningococcal, was reported from: Agawam, 1; Arlington, 2; Ashland, 1; Attleboro, 1; Ayer, 1; Boston, 19; Braintree, 2; Brockton, 2; Camp Edwards, 2; Cambridge, 2; Chelsea, 1; Chicopee, 1; Everett, 1; Fall River, 3; Fort Devens, 2; Franklin, 1; Lexington, 1; Lowell, 2; Malden, 1; Marblehead, 1; Middleboro, 1; Milford, 1; Milton, 3; Newton, 2; Norton, 1; Pittsfield, 1; Quincy, 1; Saugus, 1; Shrewsbury, 1; Somerville, 1; Sturbridge, 1; Waltham, 1; Watertown, 2; Westfield, 2; West Springfield, 1; Worcester, 1; total, 68.

Meningitis, Pfeiffer-bacillus, was reported from: Brockton, 1; New Bedford, 1; Weymouth, 2; total, 4.

Meningitis, pneumococcal, was reported from: Boston, 2; Cambridge, 1; Cohasset, 1; Norwood, 1; Salem, 1; Worcester, 1; total, 7.

Meningitis, streptococcal, was reported from: Lawrence, 1; New Bedford, 1; total, 2.

Meningitis, other forms, was reported from: Boston, 1; total, 1.

Meningitis, undetermined, was reported from: Boston, 3; Cambridge, 2; Chelsea, 1; Holyoke, 1; Quincy, 5; Westfield, 2; Worcester, 3; total, 17.

Salmonella infections were reported from: Attleboro, 1; Bedford, 1; Dartmouth, 1; Lynn, 1; Manchester, 1; Medford, 1; Newton, 7; total, 13.

Septic sore throat was reported from: Amesbury, 1; Bedford, 1; Boston, 9; Bourne, 1; Cambridge, 1; Camp Edwards, 4; Haverhill, 2; Lawrence, 3; Merrimac, 8; Newbury, 1; Newton, 2; Scituate, 1; Winchester, 1; Worcester, 2; total, 37.

Tetanus was reported from: New Bedford, 1; Quincy, 1; total, 2.

Trichinosis was reported from: Boston, 3; Chelsea, 3; total, 6.

Typhoid fever was reported from: Fall River, 1; New Bedford, 1; North Attleboro, 1; total, 3.

Undulant fever was reported from: Boston, 1; Cambridge, 1; Winchester, 1; total, 3.

MISCELLANY

DEPOT HOSPITALS FOR PENICILLIN

The following New England institutions have been selected to serve as "depot hospitals" by the Office of Civilian Penicillin Distribution, War Production Board, for the proper storage and distribution of penicillin for civilian medical use. These hospitals will be the local depots for further distribution of the drug, as well as a source of supply for their own requirements. They will recognize the request of other hospitals and, if the need is established, will, to the best of their ability in consideration of their supply on hand, furnish penicillin for purchase by such other hospitals. This list is subject to revision by action of the Advisory Panel.

NOTICES

PHI DELTA EPSILON LECTURE

Dr. Edward Weiss, professor of medicine at Temple University School of Medicine, will deliver the first annual Phi Delta Epsilon lecture at Boston University School of Medicine auditorium, on Wednesday, May 31, at 8:15 p.m. His topic will be "Psychosomatic Aspects of Cardiovascular Diseases." He will be introduced by Dr. Chester S. Keefer.

NEW ENGLAND HOSPITAL FOR WOMEN AND CHILDREN

The monthly clinical conference and meeting of the staff of the New England Hospital for Women and Children will be held on Thursday, June 1, at 7:15 p.m. in the classroom in the nurses' residence. Dr. Samuel R. Meaker will speak on the subject, "Sterility." Dr. Ilia Galleani will be chairman.

THIOURACIL IN THE TREATMENT OF THYROTOXICOSIS*

A Report of Seventy-Two Cases

ROBERT H. WILLIAMS, M.D.,† AND HOWARD M. CLUTE, M.D.‡

BOSTON

IN THYROTOXIC patients thiouracil has been found to cause a lowering of the metabolic rate to normal levels, a return to normal of the protein-bound iodine of the plasma and concurrently a clinical remission of the disease.^{1,2} The evidence accumulated suggests that these changes result from the action of the drug on the thyroid gland, decreasing in some manner the formation of its hormone. Since the appearance of the above reports we have used thiouracil§ in the treatment of 72 thyrotoxic patients, including a continuation of treatment of the 9 patients reported by Williams and Bissell.² In the course of these studies a number of observations were made concerning the progress of the disease as influenced by prolonged treatment with thiouracil, the desired dosage, the complications arising from the use of the drug, the use of thiouracil instead of iodide preoperatively and the production by thiouracil of certain anatomic and chemical changes in the thyroid gland.

The present series includes all the patients with thyrotoxicosis seen since the beginning of the study. A number of variations in the disease were found. There were examples of classic Graves's disease, toxic nodular goiter and toxic adenoma. The duration of the illness varied from three weeks to twenty-two years. Subtotal thyroidectomies had previously been performed on 13 patients. In one case this operation had been carried out three times, and in another twice. Thirteen patients had taken potassium iodide, for several weeks, discontinuing it within about a month before thiouracil therapy was begun. Most of the patients were not hospitalized for more than one day. Complete physical examinations were made, particular attention being

paid to the size, configuration and consistency of the thyroid gland and to the manifestations of exophthalmic ophthalmoplegia. Before the beginning of treatment an adequate number of determinations of the basal metabolic rate were made to indicate the degree of toxicity.

In the first 30 patients treated the initial daily dosage of thiouracil was usually 1 gm., but with subsequent patients it was 0.6 gm. daily or rarely 0.4 gm. In most cases, however, the dosage was reduced to 0.2 gm. daily over a period of about six weeks. Single doses usually consisted of 0.2 gm., although they were sometimes only 0.1 gm. When several doses were given daily, they were spaced evenly throughout the day for reasons that will be discussed later.

Almost all the patients were permitted to perform their usual duties but were asked to return to the outpatient clinic at the Boston City Hospital for observation, including a determination of the basal metabolic rate, at intervals of one or two weeks during the first six weeks of treatment, and at intervals of about four weeks thereafter. The white-cell count was usually made several times during the first six weeks, but thereafter only when the patient developed some type of infection or complained of vague weakness and malaise.

We have now treated 48 patients for more than two months, 35 for more than four months, and 16 for more than six months. Twenty-four patients have been treated for two months or less.

RESULTS OF TREATMENT

Although estimations of the clinical status of the patients were made at each visit, the thyrotoxicity can best be demonstrated by presenting the rates of basal oxygen consumption, since the results of this test were usually in accord with the observed clinical changes. Many patients maintained that a marked improvement had occurred within twenty-four to forty-eight hours after first taking thiouracil. This rapid change may have been due in part to a

§Thiouracil was supplied through the courtesy of the Lederle Laboratories, Incorporated, Pearl River, New York.

mild sedative effect of the drug, as well as to its psychologic effects.

Changes in Basal Metabolic Rate

There were 59 patients who had not received iodide treatment for more than one month before thiouracil was started and were therefore probably free of iodide effect. These cases were divided into three groups according to whether the lowest metabolic rate preceding thiouracil treatment was from +55 to 89, from +35 to 55 or from +15 to 35 per cent; there were 16, 23 and 20 patients, respectively, in each division. For each group was calculated an average of the basal metabolic rates obtained before and after thiouracil treatment and at equal intervals thereafter. These results are plotted in Figures 1, 2 and 3, together with the extreme variations in the metabolic rates and the average

FIGURE 1. The Changes in Metabolic Rate and Weight in Association with the Thiouracil Treatment of 16 Patients with Marked Thyrotoxicosis.

weight gain. In these figures are included the results obtained preoperatively in 18 patients who had a subtotal thyroidectomy. One patient felt so well after a few months of treatment that he refused any more treatment or examination. Four patients discontinued therapy for intervals of two to four weeks, and 3 of these had a slight recurrence of their disease. All these patients had a normal basal metabolism for more than a month before discontinuing treatment. One patient discontinued therapy for three weeks after having taken it for two months, but there was no relapse. Therapy was resumed; a few months later she discontinued it for one month and experienced a recurrence of the disease, but there was no thyrotoxicity within three weeks after resuming treatment. Another patient discontinued therapy after three months and experienced a relapse in three weeks; complete remission did not occur until six weeks after resuming treatment. A third patient stopped taking the drug after seven months. An exacerbation was observed in two weeks, and the metabolic rate was not found

normal until four weeks after resuming treatment. The metabolic rates during the exacerbation in these 3 patients have been omitted, but those obtained after a few weeks of resumed treatment are included.

The basal metabolism decreased under thiouracil treatment much more rapidly in the severe cases

FIGURE 2. The Changes in Metabolic Rate and Weight in Association with the Thiouracil Treatment of 23 Patients with Moderately Severe Thyrotoxicosis.

(basal metabolic rate, +55 to 89 per cent) than in the others. It did not become normal on the average, however, until after five weeks of treatment, whereas in the moderately severe cases (basal metabolic rate, +35 to 55 per cent) this interval was four weeks, and in the mild cases (basal metabolic rate, +15 to 35 per cent) only three weeks. The basal metabolic rate had become normal in each patient within an interval of ten days to seven weeks. This statement does not apply to all the

FIGURE 3. The Changes in Metabolic Rate and Weight in Association with the Thiouracil Treatment of 20 Patients with Mild Thyrotoxicosis.

cases subsequently operated on, because several of these patients were treated for less than two weeks. During the interval that they were observed, however, there was no difference in their response to therapy from that of the unoperated cases. In essentially all the patients the metabolic rate remained

normal following treatment, although occasionally a value slightly above normal was obtained that, on questioning the patient, was usually found to be related to excess work before the test, a respiratory infection or some other such extraneous factor. The slight tendency to a rise in the metabolism after about two months of treatment was probably related to reduction in dosage. In an attempt to use the minimal effective quantity of thiouracil the dosage was occasionally reduced to as little as 0.1 gm daily, which was sometimes inadequate. On the other hand, when the dosage was too large, the metabolic rate became undesirably low and the patient experienced distinct clinical manifestations of hypothyroidism. However, these changes could be rapidly altered by a slight readjustment in the dosage.

In most of the patients there was little or no gain in weight during the first two weeks of treatment. Indeed, in many cases there was an actual loss in weight. Gain in weight was rapid with four to eight weeks of treatment and gradually increased thereafter, occasionally becoming excessive.

There were 13 patients who received iodide therapy either within one month before commencing thiouracil or during its administration. Consequently, these cases are discussed separately from the foregoing 59. In Figure 4 are plotted the changes in the metabolic rate of these patients, each of whom had taken potassium iodide regularly for an interval of one month to two years, this therapy having been discontinued during a period of four weeks preceding thiouracil treatment; in this group a continued iodide effect was to be expected. At the time that the thiouracil therapy was begun the metabolic rate was normal in only one case. These patients tended to be resistant to thiouracil therapy, particularly during the first three weeks. In fact, in 3 of 5 cases in which there was an immediate transition from iodide to thiouracil therapy, a distinctly greater elevation in the metabolic rate was found two weeks later. Whereas a normal metabolism was ultimately obtained in the 5 patients treated for eight weeks or longer, this interval was distinctly longer than that required in the 59 cases previously discussed (Figs. 1, 2 and 3). This delayed response was observed even though no iodide had been given for as long as three weeks preceding thiouracil. The course of a tenth patient was apparently similar, but the data in this case are incomplete. The remaining 3 of the 13 patients received potassium iodide and thiouracil concomitantly. The response in two of these cases was about the same as one would expect from the use of thiouracil alone, whereas in the third case the metabolic rate declined very slowly; the latter patient had taken iodide for two years before beginning thiouracil treatment.

In 2 of the 59 patients already discussed, the changes in metabolic rate when the therapy was

changed from thiouracil to potassium iodide were also observed. In each case a slight exacerbation occurred.

Changes in Protein-Bound Iodine Content of Plasma

Although the accurate determination of the protein-bound iodine* content of the plasma represents one of the best methods of estimating the

FIGURE 4. The Changes in Metabolic Rate and Weight in Association with the Treatment of 9 Patients with Thyrotoxicosis Who Had Previously Been Given Potassium Iodide. Note that the decrease in metabolic rate, as well as the gain in weight, took place more slowly than it did in those who had previously received no iodide therapy (Figs. 1, 2 and 3).

amount of thyroid hormone produced, the procedure involved is long and tedious and thereby tends to reduce extensive use. Nevertheless, in some cases the changes induced in this fraction by thiouracil therapy have been followed, the method of Riggs

FIGURE 5. The Changes in the Concentration of the Protein-Bound Iodine of the Plasma Compared with those in the Basal Metabolic Rate following Thiouracil Treatment.

Patient F. C. had a colloid goiter, B. F. had myxedema, and the others had thyrotoxicosis. The dosage of thiouracil was, for the most part, 1 gm. daily.

and Man³ being used. The normal range is from 4 to 8 gammas per 100 cc. A few of the results have previously been reported.²

As shown in Figure 5, the protein-bound iodine returned to normal in each of the thyrotoxic patients in whom the determination was done. Indeed,

*The protein-bound iodine is composed of the so-called "D" and "T" iodines, which are essentially equivalent, respectively, to the di-iodotyrosine and the thyroxine content of the plasma.

in 2 subjects it reached the myxedema range. The data are sufficient to show that in at least 4 cases the iodine level became normal before the metabolic rate did. If this principle held in most cases, one would expect the plasma protein iodine to be normal in the majority of patients in about four weeks or less. The level was essentially normal in 2 cases within four weeks and in 2 others within two weeks. In 2 subjects estimations were made as long as twelve weeks after beginning thiouracil treatment, and in each case the iodine concentration was well within normal limits.

No change in the plasma protein iodine occurred in a patient with colloid goiter (F. C.) who was treated with 1 gm. of thiouracil daily for three weeks; nor did any definite change occur in a myxedematous subject (B. F.) similarly treated for two weeks.

One patient who stated that she had taken 15 drops of potassium iodide daily for two years had a basal metabolic rate of +44 per cent and a thyroxinlike iodine concentration in the plasma of 11.6 gammas per 100 cc. She was treated with 0.4 gm. of thiouracil daily. Five weeks later the basal metabolism was +15 per cent and the thyroxinlike iodine was 6.9 gammas per 100 cc. Thus, whereas this patient was not well controlled with iodide, she showed a distinct improvement when thiouracil therapy was given concomitantly with the iodide, although the response was slower than is generally the case when thiouracil alone is used.

Changes in Thyroid Gland

The changes in the size and consistence of the thyroid gland are difficult to discern. Nevertheless, attempts were made to evaluate these factors at each visit of the patient. An increase in the size of the gland was observed in 11 patients during the first few weeks of treatment with thiouracil. The consistence of these glands, as well as those of some other patients, became firmer soon after thiouracil was started. In 2 cases the thyroid gland was distinctly larger than it was cases no change

In most of the patients, however, a distinct decrease in the size of the thyroid gland was observed after more than six weeks of treatment with thiouracil, and in 21 cases there was a 33 to 66 per cent decrease. In a few cases glands that were formerly two to three times normal size and of firm consistence returned to an essentially normal state. In

desiccated thyroid was used for several weeks in doses of 0.5 to 1.5 gr. daily to reduce the size of the thyroid gland. In most of the cases such treatment proved to be of advantage.

Ocular Changes

Five patients initially exhibited changes in the orbits characteristic of those found with malignant

exophthalmos.⁴ In each case the manifestations became worse during the first few weeks of treatment with thiouracil, and in 1 case they became severe, the patient developing marked palpebral edema, conjunctival injection and chemosis, marked lacrimation and several corneal ulcers. Desiccated thyroid was used in the treatment of these subjects after the metabolic rate had become normal under thiouracil therapy. The rationale of this treatment will be discussed later.

All the patients who exhibited a stare and widened palpebral fissures experienced a distinct improvement in these disturbances as the metabolism became normal. Many patients stated that their eyes were "looking normal again."

Complications

The most serious complication encountered was leukopenia with agranulocytosis, which was experienced by 1 patient. This was discovered at the end of six weeks of treatment, during which the patient received 0.6 gm. of thiouracil daily for the first two weeks, 0.4 gm. daily for the next two weeks and 0.2 gm. daily for the last two weeks. A white-cell count was made when the patient complained of fever and an infected finger. She was treated with Pentnucleotide and large doses of crude liver extract. Complete recovery resulted, although only a few granulocytes were present for a period of seven days. In another case the white-cell count dropped to 3200, with 20 per cent granulocytes; only a few days after beginning thiouracil treatment. In spite of continued therapy, however, the white-cell count returned to normal and the granulocytes increased to 50 per cent. Subsequently, the patient took thiouracil for more than six months and remained in good health. Leukopenia and granulocytopenia were seen in some other cases, but the incidence was apparently no greater than that observed in untreated thyrotoxic patients.¹⁷ Four patients developed a morbilliform rash associated with itching, but this disappeared in spite of continued treatment. Three others developed moderately severe urticaria. One of these patients discontinued thiouracil for three days and then resumed it without recurrence. Another with urticaria developed painful swollen and stiff joints lasting one week. Following this episode iodide therapy was substituted. The third patient developed urticaria and fever after eight months of thiouracil therapy and a thyroidectomy was then performed. Six patients developed swelling of the legs that was not associated with hypoproteinemias, cardiac failure or evidence of renal damage, but data obtained from some of these patients, as well as others, indicate that thiouracil in certain dosages may cause a retention of sodium, chloride and water. A decrease in the carbon dioxide combining power of the blood was also found in a few of these patients, but

these changes disappeared in spite of continued therapy.

Two patients experienced nausea and vomiting during the first week of treatment, but these symptoms disappeared without stopping of the medication. Another patient had swelling and soreness of

of whom had received thiouracil preoperatively in amounts and for periods of time designated in Table 1. The colloid goiters were removed chiefly because of their large size, as was the case in 4 thyrotoxic cases. In 6 cases the gland was removed because the patient desired this treatment at the

the submaxillary salivary glands, which subsided without alteration of the treatment.

In summary, untoward reactions of some sort, ranging from mild to severe, occurred in 13 of the 72 patients treated. In only 3 were these reactions of such severity as to necessitate discontinuation of the drug, although in some cases therapy was omitted until the symptoms ceased.

THYROIDECTOMY FOLLOWING THIOURACIL TREATMENT

A thyroidectomy was performed on 22 thyrotoxic patients and on 3 patients with colloid goiters, each

outset. In 11 cases it was removed because such factors as distant residence or business obligations interfered with adequate observations. The gland was removed from 1 patient after she had developed urticaria that was apparently due to thiouracil. However, in no case was a thyroidectomy performed because of any evidence that the metabolic rate could not return to normal with the use of thiouracil alone. In fact, in 13 of these 22 patients the basal metabolism was normal at the time of the operation. Eight of the other 9 patients had received treatment for less than four weeks, but during this interval they showed the usual lowering of the basal

metabolic rate that occurred in the nonoperated group. The remaining patient had a basal metabolism of +17 per cent at the time of operation, having received thiouracil for five weeks. Judging from the course of other cases, however, the rate would most likely have been normal within another week.

The actual duration of thiouracil treatment preceding operation varied from one day to two hundred

99 to 102°F., averaging 100.7°F. The postoperative period of hospitalization varied from five to fifteen days, averaging eight days. On the whole, the course of the patients during and following the operation was relatively smooth in all but 3 cases, these patients being excited and restless. In none of the latter cases had thiouracil been given for as long as ten days. In general, the patients treated with thiouracil and without iodine for as long as

FIGURE 6. Section of Thyroid Gland of a Thyrotoxic Patient Treated with Thiouracil for Twenty-Three Days.

Note the scanty colloid and the great mass of cells. Most of the colloid is quite pale, although a few deep-staining clumps are seen in the right lower corner. The cells are hyperplastic, and the lumens of many acini are largely obliterated. Increased interstitial tissue is observed in some areas.

and forty days, and the daily dosage was usually 0.4 or 0.6 gm. Some of the patients had iodine therapy either before, during or after the thiouracil therapy, as noted in Table 1. One patient was operated on in two stages under cyclopropane and ether anesthesia. There were no greater technical difficulties in the removal of the gland after thiouracil therapy than exist after iodide therapy, except for slightly more vascularity and friability of the tissue. The maximal pulse rate during the operation varied from 80 to 180, averaging 123. In 16 subjects it never exceeded 130. The highest systolic blood pressure varied from 135 to 220, averaging 169, and the highest diastolic pressure varied from 70 to 130, averaging 95. Of course, almost throughout the operation in each case the pulse rate and blood pressure remained at distinctly lower levels than indicated above. The maximal pulse rate following the operation varied from 88 to 140, averaging 110, and the maximal temperature ranged from

three or four weeks had an extremely smooth course.

It is much too early to evaluate the results of operation, although with the short periods of observation made thus far there has been no evidence of persistence or recurrence of toxicity.

ANATOMIC AND CHEMICAL CHANGES IN THYROID GLAND

Anatomic Changes

The thyroid glands of patients who received thiouracil for more than two weeks were distinctly firmer than normal, having a rubbery consistence. The cut surface was uniformly grayish-yellow, with a slightly pink hue. Many of the glands had little visible colloid and were more friable than normal. On microscopic examination a moderate variation in the structure of the gland was found. In the group of patients who received no iodide at any time but were treated with thiouracil for intervals of

eight to thirty-two days, it was found in general that the longer the drug had been given the greater the thiouracil effect (Fig. 6). Glands showing this effect to a pronounced degree possessed many or all the following characteristics. A marked scarcity of colloid was readily noted, the tissue consisting of an almost solid sheet of cells in many areas. The colloid that was present tended to be quite pale. Many acini appeared small and contracted, the lumen having almost entirely disappeared. On the other hand, a few acini had an enlarged lumen and these were apt to show papillary projections. The cells were tall and columnar. There was an increase in the interstitial tissue, with a noticeable increase in fibroblasts, lymphocytes and collagen. In some areas there were foci of dense lymphocytic infiltration ramifying between the acini in a disorderly manner, but it was commoner to observe well-circumscribed lymph follicles, many with prominent germinal centers, consisting of lymphoblasts in the center with a few clumps of collagen and an occasional macrophage, all densely surrounded by lymphocytes. These lymph follicles were usually subcapsular. They were present in about half the cases, and were larger and more prominent than the occasional cluster of lymphocytes commonly seen in the thyroid gland.

Changes were seen varying in degree from the ones described above to those of an untreated thyrotoxic gland. In no case, however, was there anything resembling the appearance of iodized glands. There was no striking difference in the appearance of the glands of the 2 patients treated for three months and eight months, respectively, from that of the glands of certain patients treated for only one month.

It was of interest to note that in a case treated with thiouracil for twenty-four days, during the last fourteen days of which potassium iodide was also given, the gland showed a classic iodine effect with no evidence of a thiouracil effect. A patient who also took thiouracil for five days, nothing for the next three days and then potassium iodide for the next nine days was found to have no definite iodine effect in the thyroid, the gland appearing like an untreated thyrotoxic gland with perhaps a slight thiouracil effect.

One patient was given iodide for six weeks, during the last nine days of which thiouracil was given. The latter drug was continued until a hemithyroidectomy was performed seventeen days later. The gland showed a large amount of moderately deep-stained colloid and slight hyperplasia of the acinar cells. Thiouracil treatment was continued, and forty-two days later a second operation was performed. The tissue removed at this operation showed less colloid but more hyperplasia than did the portion removed at the first one. It seems probable that the iodide therapy influenced the effects of thiouracil long after the former had been dis-

continued. Two other patients exhibited this same phenomenon to some extent.

Changes in Concentration of Thyroxin Iodine

In 11 thyrotoxic cases about two thirds of each thyroid gland was analyzed for its thyroxin iodine content by the method of Leland and Foster.⁶ The results were compared with those given by Gutman, Benedict, Baxter and Palmer⁷ for normal glands, iodized exophthalmic glands and noniodized exophthalmic glands. The glands of 7 patients treated with thiouracil and no iodide had distinctly less thyroxin iodine than did those of patients who received no treatment (Fig. 7). There was an ex-

FIGURE 7. Thyroxin Iodine in Thyroid Glands (micrograms per gram dry tissue).

The average values for the normal glands and for the iodized exophthalmic glands were taken from Gutman and his co-workers,⁷ and the average value for the noniodized exophthalmic glands was calculated by these authors from the data of Wilson and Kendall.⁸ Patients B. O., L. A., and B. A. had had some iodide therapy before thiouracil treatment was begun. The results of a two-stage operation are given for patient L. A. Patient M. U. had no iodide until a day and a half before thyroidectomy, a relatively high concentration of thyroxin iodine was present. Note especially the small concentration of thyroxin iodine in the glands of patients treated with thiouracil and no iodide.

extremely small amount of thyroxin iodine in the thiouracil-treated glands, as compared with the quantity in normal or iodized exophthalmic glands. Of the 4 patients who had received iodide therapy, one patient (B. A.) had a large amount of thyroxin iodine in the gland although she had had no iodide for five weeks. On the other hand, another patient (B. O.) with a similar schedule of treatment had less thyroxin iodine than the average amount in nontreated exophthalmic glands. One patient (M. U.) who had never had iodide treatment except for the day and a half preceding operation had a relatively large concentration of thyroxin iodine in her gland. The fourth subject (L. A.), who was treated with iodide for six weeks, ending ten days before hemithyroidectomy, had essentially the same concentration of thyroxin iodine as in the average untreated exophthalmic gland. Although

after forty-two days of additional thiouracil treatment the amount of iodine in the second half of the gland had decreased, it was still larger than that found in the glands of patients who had received thiouracil and no iodide.

Concentration of Thiouracil

Immediately after removal of the thyroid gland an analysis was begun to determine the concentration of thiouracil therein, using the method of Williams, Jandorf and Kay.⁹ In the patients who had continued thiouracil therapy until the day of operation, the values ranged from 5 to 39 mg. per 100 gm. of dried gland. A patient (T. R.) who had had no treatment for seven days preoperatively was found to have 14 mg. per cent. Patients treated for as long as fifteen days tended to have as great a concentration as did those treated for longer intervals. Previous iodide therapy had no effect on the amount of thiouracil present, but 3 patients treated with thiouracil alone and then given iodide therapy during the day preceding operation obtained a higher average level than did the other patients. The variations in thiouracil concentration were not associated with any consistent alterations in histologic structure. Furthermore, they did not correlate with the concentrations of thyroxin iodine in the thyroid gland or with the clinical response.

An effort was made to ascertain whether thiouracil was stored equally in the colloid and in the parenchyma. In 6 cases, a portion of the gland was sectioned into several large pieces and these were gently squeezed by a metal compressor. By this procedure, which is admittedly crude, it was hoped to express some colloid and not many cells or tissue fluid. The fluid so obtained in the 6 cases contained a concentration of thiouracil distinctly greater than that of the whole gland, when expressed in terms of dry weight (Table 1). Two glands were given a second and a much firmer compression with the hope of obtaining a moderate amount of tissue fluid. This fluid and the residual tissue were separately analyzed for the concentration of thiouracil. The tissue fluid had a higher concentration of thiouracil than did the residual tissue (Table 2). When the quantity of thiouracil was ex-

The problem of the distribution of thiouracil between colloid and cells was also approached by comparing its concentration in glands containing little colloid with that in those containing moderate amounts. No significant differences were found.

DISCUSSION

The experiences reported here in the treatment of thyrotoxicosis with thiouracil indicate that this drug can be depended on in essentially all cases to lower the basal metabolic rate to a normal range and to maintain it at that level so long as treatment is continued. Associated with this response in the basal metabolic rate is a clinical remission of the disease, with disappearance of tachycardia, hyperidrosis, nervousness, diarrhea, weight loss and other toxic manifestations.

Thiouracil causes a decrease in the protein-bound iodine of the blood and in the thyroxin iodine of the thyroid gland, but does not inhibit the hypermetabolic effects of preformed thyroxin.² These facts indicate that thiouracil inhibits the production of the thyroid hormone, but the exact process by which this is accomplished has not yet been determined. Presumably, when the production of the thyroid hormone is markedly inhibited, there results an excessive production of thyrotropic hormone, which in turn causes hyperplasia of the acinar cells of the thyroid and certain manifestations of malignant exophthalmos.⁴ Thus, as we have observed in several cases, with the use of thiouracil in excessive quantities in thyrotoxic patients a still greater enlargement of the thyroid gland may result and the manifestations of malignant exophthalmos may be accentuated. Under such circumstances it is advisable to reduce the dosage of thiouracil. In some cases, however, the use of desiccated thyroid also seems indicated, since it not only inhibits the production of thyrotropic hormone but also exerts a diuretic effect that is of advantage in the control of the severe cases of malignant exophthalmos. To be sure, on theoretical grounds one may argue that the same thing can be accomplished by permitting the patient's own thyroid gland to manufacture more hormone. Nevertheless, we have thus far had better success by decreasing the thiouracil to a sufficiently small dosage to maintain a normal metabolic rate and then giving 1 to 1.5 gr. of desiccated thyroid daily. Before adopting this policy, however, we first sought to discover whether thiouracil would inhibit the inactivation of administered thyroid, it having been shown¹⁰ that persons with normal thyroid glands can inactivate large quantities of desiccated thyroid or thyroxin.

To elucidate this problem 3 patients were treated with relatively large doses of desiccated thyroid for intervals of thirty to fifty days, during the last two or three weeks of which 0.6 gm. of thiouracil was administered daily. No significant changes in the basal metabolic rate occurred in any of these pa-

TABLE 2. Distribution of Thiouracil in the Thyroid Gland.

pressed in terms of wet weight there was only a slightly greater concentration in the colloid than was present in the gland as a whole.

tients (Fig. 8). Furthermore, the thyroxinlike iodine of the plasma, determined in 1 case (D. U.) actually decreased following the thiouracil treatment.

Clinical studies were also conducted that indicated that thiouracil can inhibit the effect of relatively large amounts of thyrotropic hormone in increasing the production of thyroid hormone. Williams and Bissell² found that when 1 gm. of

FIGURE 8. Basal Metabolic Rates in 3 Patients without Thyroid Disease Treated Simultaneously with Thiouracil and Desiccated Thyroid.

Note that no significant change in the basal metabolic rate resulted from large doses of desiccated thyroid whether or not thiouracil (0.6 gm. daily) was also given. A slight decrease in the thyroxin iodine (expressed in micrograms per 100 cc) of the plasma resulted in one case (Patient D. U.)

thiouracil was given daily with 2 cc. of thyrotropic hormone (Antuitrin T) in sesame oil to a normal subject for a period of ten days, no elevation in the basal metabolism resulted, although a goitrogenic effect was noted. Subsequent unpublished studies showed that no change results in the concentration of the protein-bound iodine of the plasma. This experiment was repeated in another normal subject using the same amount of thyrotropic hormone for eight days but no thiouracil. Although no significant elevation in the metabolic rate occurred, the plasma iodine showed a marked rise, increasing from 8 to 15 gammas per 100 cc. Thus, the marked inhibitory effect of thiouracil in the first case is apparent.

In choosing the ideal dosage of thiouracil it is desirable to use the smallest amount necessary to obtain a remission of the disease, but it has been found that this quantity varies with different patients. In an attempt to establish an objective method of ascertaining this dosage, Williams, Kay

and Jandorf¹¹ determined in a large number of cases the concentration of thiouracil in the blood when the patient was given from 0.2 to 1.2 gm. daily. The blood level remained relatively constant, regardless of what dose was given. Furthermore, using the above range of doses we have found no directly proportional concentration of the drug in the thyroid gland. In the course of varying the dosage, however, the amount of drug necessary to obtain an adequate response in thyrotoxicity was distinctly less than the amount that was first used.^{1, 2} An outline of treatment with thiouracil that we have found extremely satisfactory is the following: 0.2 gm. three times daily for the first two weeks, followed by 0.2 gm. twice daily until the metabolism is normal and then 0.1 gm. twice daily until the basal rate has been maintained well within normal limits for several weeks, when the dosage can be reduced to 0.1 gm. daily. Cases have rarely been encountered in which larger doses were necessary, and in a number of cases smaller ones were used. Whatever schedule of dosage is to be used, it should be borne in mind that thiouracil is rapidly absorbed and excreted.¹¹ Thus, it is better to give two or three decreased doses per day than it is to give only one. On the other hand, the prescription of many small doses may cause the patient to become quite irregular in taking treatment.

Williams, Kay and Jandorf¹¹ found that the routine estimation of the thiouracil content of the blood and urine was of no definite aid in treatment. Most of the tissues of the body can break down large amounts of thiouracil, thereby interfering with its accumulation in the blood of normal subjects as well as of patients with severe disease of the heart, kidneys or liver.

Of the various complications thus far encountered, the only one to cause appreciable concern is agranulocytosis. Patients who develop urticaria or any other allergic manifestation, however, should be carefully observed when treatment is resumed, since other sensitivity phenomena may result.

Much more must be learned before the role of thiouracil in the medical treatment of thyrotoxicosis can be fully evaluated. In most cases its great dependability in controlling the toxicity makes hospitalization unnecessary. Furthermore, the majority of patients can continue regularly with their work. Nevertheless, patients treated in this manner should maintain close contact with the physician, particularly during the first two months. How many patients can discontinue therapy without a relapse in the disease remains to be demonstrated. The prolonged course of treatment does not of itself constitute much of a burden, since the maintenance dosage does not have to be varied much once it has been properly estimated. The possibility of chronic complications and the development of therapeutic unresponsiveness to the drug must be borne in mind, although we have thus far seen no evidence.

By accurately regulating the dosage of thiouracil it is believed that the goitrogenic effect can be kept low. In fact, in most cases the gland tends to decrease in size. Two reasons for this decrease may be advanced: a marked decrease in the content of colloid, permitting a collapse of the acini, and an exhaustive phenomenon — an atrophy of the cells resulting from the prolonged stimulation by the thyrotropic hormone. The first phenomenon was often observed in our patients, but no evidence of the second has yet appeared.

In spite of the fact that many thyroid glands have decreased in size with treatment, it is not considered advisable to give prolonged thiouracil treatment to a patient who has an extremely large gland, since there is some possibility that the gland will actually become larger. Since some of these patients have compression of the surrounding structures, the risk of further trouble should not be taken. However, the drug has been used preoperatively in some patients with extremely large glands. In fact, the gland of one patient weighed 500 gm. at operation in spite of a decrease in the neck circumference of 2.5 cm. during treatment. In this case, as in somewhat similar ones, desiccated thyroid was used with the thiouracil.

Thus far, we have not found that iodide used preceding or during thiouracil treatment is of any advantage. In fact, the patients who had iodide previously responded more slowly to thiouracil than did those who had not had any. Furthermore, in some cases there was actually an exacerbation of the disease if thiouracil was suddenly exchanged for iodide. This is to be expected when one considers that iodide causes storage of the hormone in the thyroid gland, whereas thiouracil apparently does not possess this action and thereby permits escape of the stored hormone into the blood stream. Bearing these phenomena in mind, when our patients are changed from iodide to thiouracil therapy, the treatments are overlapped for about two weeks, the amount of iodide therapy during this interval being progressively decreased.

There is evidence from studies in guinea pigs that the simultaneous administration of potassium iodide and thiouracil causes a greater concentration of the latter in the thyroid gland than occurs when the iodide is omitted.¹² On the other hand, in rats after thiouracil has been given for several days the uptake of radioactive iodine in the thyroid gland is decreased.¹³ Nevertheless, in a patient who was treated with thiouracil for three weeks and given iodide for 1.5 days preoperatively, a distinctly greater quantity of thyroxine iodine was found in the thyroid gland than in cases treated similarly with thiouracil without iodide.

The use of thiouracil in preoperative preparation has the advantage over iodine of dependability in causing a disappearance of the toxic manifestations of the disease in essentially every case, provided

that the treatment is continued for several weeks. Because of this dependability the patient may be permitted, in most cases, to perform a part or all of his usual activities during the period of preparation for the operation. Of course, during this interval adequate rest and a high-caloric diet supplemented by moderate amounts of vitamins, particularly thiamine and the members of the vitamin B complex, are desirable. A period of preparation of four to five weeks has thus far proved satisfactory. Since thiouracil decreases the quantity of thyroxine in the thyroid gland, in cases treated with this drug there is potentially less thyroxine to get into the blood stream at the time of operation than in the cases treated with potassium iodide.

SUMMARY

The results of treatment with thiouracil of 72 thyrotoxic patients are given.

The subjects who had not had iodide therapy for one month or more (59 cases) were arbitrarily divided into three classes according to the height of the basal metabolic rate preceding treatment. The decline in the basal rate was more rapid in the severe cases (basal metabolic rate, +55 to 89 per cent) than in the others, but required an average of five weeks to become normal, whereas in the moderately severe cases (basal metabolic rate, +35 to 55 per cent) only four weeks was necessary, and in the mild ones (basal metabolic rate, +15 to 35 per cent) only three weeks. The lowering of the basal metabolic rate in patients who had taken iodide until the thiouracil treatment was started was slower. All patients, however, regardless of the type of thyrotoxicity or of previous treatment, eventually attained a normal metabolic rate and a remission of the disorder.

Thirty-five patients were treated with thiouracil for more than four months and 16 for more than six months. Essentially all patients maintained a normal basal metabolism. In 4 patients who discontinued therapy after a few months, a relapse occurred in about three weeks, but a remission was again obtained with thiouracil treatment.

In the few cases where the plasma protein iodine content was determined this value became normal and tended to do so before the metabolic rate became normal. Although a transient increase in the size of the thyroid gland occurred in several cases, in the majority an ultimate decrease in the size of the gland resulted, this change being marked in some subjects. A few patients with malignant exophthalmos experienced an exacerbation in this process under thiouracil therapy, but with a decrease in the dosage of thiouracil and the use of desiccated thyroid an improvement resulted.

One patient developed agranulocytosis; other complications consisted of morbilliform rash, urticaria, allergic arthritis, edema of the legs, vomiting and enlargement of the submaxillary salivary glands.

Although many estimations were made of the content of thiouracil in the blood and urine, these determinations are not necessary, since with the range of dosage employed the drug has not been found to accumulate appreciably in the blood, in spite of the presence of severe disease of the kidneys and liver.

For reasons other than an unsatisfactory response in the toxic manifestations of the disease 22 patients were subjected to thyroidectomy. The operative and postoperative course was relatively smooth, particularly in the patients treated with thiouracil for three weeks or longer preceding operation. A chemical analysis of these glands for the concentration of thiouracil showed a great variation in the amount of drug present. With these cases there was no correlation of the therapeutic response with the level of the drug in the gland. The thyroxine iodine was found to be extremely low in most of the glands that were analyzed. The pathologic alterations in the thyroid gland resulting from thiouracil treatment are described; they are quite unlike the changes found after iodide therapy.

We are indebted to Drs. T. J. Anglem, F. R. Kenny, G. W. Bissell, A. R. Weinglass, R. I. Smith, M. L. Bradford, R.

Mankowich and W. A. Dafoe, for clinical assistance, and to the Misses J. B. Peters and G. A. Kay for the chemical determinations.

FAVUS IN MASSACHUSETTS*

A Report of Two Cases

GEORGE E. MORRIS, M.D.†

BOSTON

FAVUS is a rare fungus infection, and only a few cases of it have been reported from Massachusetts. Search of the records of the Boston City Hospital revealed that no cases had been seen there during the last ten years. This report of 2 cases is of interest, first because of the rarity of the disease, and second because of the satisfactory response to therapy.

The disease is usually caused by *Achorion schönleini*, but on rare occasions *A. quinckeanum* has proved to be the etiologic agent. The fungus may be found in or on the hairs, in the scutula and in and on the skin and nails. Microscopically the hairs, when softened in 30 per cent potassium hydroxide solution, show a characteristic diagnostic picture. They are usually covered with air bubbles, which are thought to be the result of displacement of air in the dead fungic filaments by the potassium hydroxide solution. On the outside, both spores and filamentous forms occur; within the hairs, coarse mycelial threads, usually broken into oblong bars

and into chains of spores (arthrospores), are found running parallel to the long axis of the hairs. These intrapilar filaments and spores are coarser and fewer than are those seen in Trichophyton infections, and favus spores are two to three times larger than are the spores seen in Microsporon infections (Fig. 1).

The scutula, which may be found on the scalp or glabrous skin, comprise almost pure cultures of the organism. Achorion is the only pathogenic fungus that grows on the skin in such pure form.¹

On Sabouraud's medium, the organism grows slowly to form a discoid, smooth, waxy or semi-translucent, convoluted, yellowish-brown colony that frequently grows deeply into the medium, causing large fissures to occur in it. Microscopically the culture shows coarse, septate and branched filaments with numerous chlamydospores, arthrospores, terminal clubs and favic "chandeliers" (Fig. 2).

CASE REPORTS

CASE 1. E. S., an 18-year-old girl of Jewish parentage, was first seen at the Out-Patient Department of the Boston City Hospital in August, 1941, complaining of a rash on the scalp of 2 years' duration. This had started as a small spot of baldness and had enlarged despite various local applica-

tions prescribed by several physicians. The parents were born in Lithuania and had come to America 9 years prior to the birth of the patient. The latter was born in Pennsylvania and had lived there during the first 14 years of life, after which the family moved to Massachusetts.

Physical examination revealed an irregularly rounded area of patchy alopecia approximately 10 cm. in diameter over the vertex of the scalp. Many of the hairs in this area were

FIGURE 1. Hair in Potassium Hydroxide Solution, Showing Chains of Spores within the Hair.

dull and bent at acute angles, and some were broken off about 2 cm. from the scalp. There were several sulfur-yellow scutula, each pierced by a hair, adhering to the skin, which showed areas of atrophy and scarring. Examination of the scalp under a Wood's filter* revealed the yellowish-green fluorescence that is characteristic of hairs infected with Achorion.

Microscopic examination of hairs softened with potassium hydroxide solution revealed the characteristic picture of favus, and subsequent culture showed the presence of *A. schönleini*.

Examination of the other members of the family revealed no evidence of active or healed infection with Achorion.

CASE 2. J. C., a 17-year-old girl of Italian parentage, entered the Out-Patient Department of the Boston City Hospital in July, 1942, complaining of a "rash" of the scalp of 4 years' duration, which had steadily progressed despite numerous forms of local therapy. The patient was born in Massachusetts and had never been outside the Commonwealth. Her father and mother had migrated from Italy 7 years prior to her birth.

Physical examination revealed three irregularly rounded areas of patchy alopecia involving almost the entire vertex of the scalp. The hairs of these areas were lusterless, thickened and fragile. Many were broken off close to the skin, which was studded with sulfur-yellow scutula and crusts. There were areas of scarring and atrophy of the underlying epidermis. The left leg, close to the knee, showed a single rounded, sulfur-yellow scutulum, 8 mm. in diameter, adhering to the skin.

The infected hairs showed the characteristic greenish-yellow fluorescence under the Wood's filter. *A. schönleini* was cultured from the scalp and from the scutulum on the leg.

Examination of the other members of the family revealed no evidence of active or healed infection with Achorion.

*The Wood's filter is obtained by passing ordinary ultraviolet light from a mercury-vapor or carbon-arc lamp through glass that is so constructed that it absorbs all visible light (wave lengths 0.4100 to 0.7600 microns) but passes wave lengths between 0.3100 and 0.4100 microns. The best glass for dermatologic use is one whose maximum transmission lies between 0.3600 and 0.3700 microns. Such a piece of glass, suitably cut, may be fitted into a light-imperious cloth hood, which is placed over the source of the ultraviolet light. Examination is carried out in a dark room. Such a filter permits easy identification of hairs infected with fungi.

Therapy of favus of the scalp is notoriously difficult. Sutton and Sutton² state that x-ray therapy constitutes the most reliable and efficient remedy, and Ormsby and Montgomery³ assert that such therapy offers the best method of treatment, without which months and years are consumed in effecting relief. Despite the opinion of these and other authorities, x-ray epilation is not a universally successful method of treatment; for Muskatblit⁴ treated 3 cases of favus in this manner, with recurrence of the infection in all of them. A fourth case was treated with thallium by mouth. Successful epilation of the hairs followed this medication, but recurrence of the favus also occurred in this case. Muskatblit states that in his experience recurrence is common after such epilatory procedures.

Similar failure of roentgen-ray epilation to cure a patient previously under my care led to an extensive search for other more effective methods of therapy.

Trained mycologists are aware that cultures of various fungi may be killed by applying a few drops of formalin to the cotton stoppers of the tubes. The formalin decolorizes the fungi, so that the killed culture loses the characteristic and often diagnostic pigmentation of the living organisms and, incidentally, makes it valueless for teaching purposes. Such a solution, however, cannot be safely applied to the skin, for the aldehydes are well-known skin sensitizers and irritants.⁵ I found that a solution of 10 per cent thymol in chloroform would kill but

FIGURE 2. Stained Culture of *Achorion schönleini*, Showing Segmented Filaments, Terminal Clubs and Favus "Chandeliers."

not decolorize cultures of fungi. Since thymol does not sensitize and irritate the skin as does formalin, it was used as a therapeutic agent in these cases, being applied twice daily to the affected parts.

The patients were advised to shampoo the scalp twice weekly, and for the first three months used

the above prescription exclusively. They were instructed to epilate the hairs manually from the affected parts, and once weekly this procedure was supplemented by manual epilation under a Wood's filter at the clinic. Progress was satisfactory from the first, the patients experiencing less irritation and less scaling within two weeks of starting therapy. At the end of the third month, when it was thought that an irritant might stimulate the tissues to the formation of antibodies, it was decided to alternate the thymol with 4 per cent chrysarobin in chloroform, chrysarobin being an effective irritant and antiparasitic.

Therapy was continued for a year in each case, at the end of which time regrowth of hair was permitted. The thymol solution was applied twice weekly during the period of regrowth. Repeated examinations under a Wood's filter have failed to reveal any fluorescence. Microscopic examinations and cultures have failed to reveal the presence of the fungus over a period of one year in Case I and

a period of three months in Case 2. Regrowth of normal hair has occurred in many parts of the previously affected areas.

SUMMARY

Two cases of favus are reported that had apparently been acquired in Massachusetts.

The microscopic and cultural characteristics of the Achorion responsible for the disease are outlined.

A method of therapy that proved successful is described.

MEDICAL PROGRESS

ENDOSCOPY (Concluded)*

EDWARD B. BENEDICT, M.D.†

BOSTON

ESOPHAGOSCOPY

Surgery. In an editorial on Russian surgeons and Russian surgery,³⁸ it is reported that surgery is done on a vast scale in Russia. It is stated that Yudin performed in one morning three operations of replacement of esophageal stricture by jejunum. This is certainly an amazing feat.

Carcinoma. Carcinoma of the esophagus is said to be seventh in frequency in types of carcinoma among males. Operative treatment is the only method of cure. With improved technic any segment of the esophagus can now be successfully removed surgically. As pointed out in the last year's report,¹ Wooley³⁹ has discussed a technic for removing the hypopharynx and upper esophagus. Early diagnosis is the most important factor in obtaining cure. All patients with difficulty in swallowing should have early x-ray examination and esophagoscopy with biopsy to establish a positive diagnosis.

Smithers, Clarkson and Strong⁴⁰ report in detail 54 cases of carcinoma of the esophagus in which roentgenologic therapy was given. Strikingly favorable responses were noted in many cases, and most of the patients showed improvement.

Pohle and Benson⁴¹ also report on the results of radiation therapy in 85 cases of cancer of the esophagus. There were no cures. One patient, however, with cancer at the upper end of the esophagus treated by roentgenologic irradiation alone was alive and well for more than four years, and another treated by roentgenologic irradiation and implantation of radon seeds was alive and well for more than seven years. In both cases the diagnosis was confirmed histopathologically.

Benign tumor. Adams⁴² reports an interesting case of fibroma of the esophagus in a forty-one-year-old woman who complained of difficulty in swallowing of seven years' duration. After a preliminary x-ray examination and esophagoscopy, a gastrostomy was performed and a tumor measuring 5 by 7 cm. was removed by the transthoracic route. Compared with cancer, dysphagia is much slower to appear.

Pain. Moersch and Miller⁴³ point out that esophageal pain may occur in a variety of esophageal disturbances. It varies in character, intensity and distribution. It is influenced by many extraneous factors and may closely mimic the symptoms produced by other types of serious organic disease. One of the greatest obstacles in the clear understanding of the problem of esophageal pain is the lack of knowledge concerning innervation of

*From the Massachusetts General Hospital.
†Instructor in surgery, Harvard Medical School, associate visiting surgeon, Massachusetts General Hospital.

Peptic ulcer. Allison, Johnstone and Royce⁴⁴ report 10 cases of simple peptic ulcer of the lower end of the esophagus. All the patients complained of dysphagia, and in each case the cause was found to be cicatricial stenosis of the esophagus and simple ulceration, the latter being associated with chronic esophagitis and chronic gastritis. In each case the narrowing of the esophagus was associated with shortening so that a part of the stomach was pulled up into the mediastinum. The suggestion is made that this deformity, usually referred to as "congenitally short esophagus," may be acquired as the result of ulceration and scarring.

Cleaver⁴⁵ reports 10 cases of peptic ulcer of the esophagus, with pain, hematemesis and dysphagia. The pain was usually in the region of the epigastrium and at times radiated forward and around to the back. Rapid, fatal hemorrhage owing to erosion of the aorta rarely occurred; bleeding was usually much less severe. Dysphagia was mild or severe, and swallowing finally became impossible. Two complications were usually seen: perforation of the ulcer into the pleura, pericardium or bronchus and acute mediastinitis due to spread of infection from the ulcer into the surrounding tissues. The diagnosis was generally based on the symptoms and x-ray findings on swallowing barium. Esophagoscopy, although not mentioned in the summary, is considered indispensable in the differential diagnosis.

Scleroderma. Lindsay, Templeton and Rothman⁴⁶ have collected 16 cases of diffuse scleroderma, in all of which there was difficulty in swallowing. They had 5 patients of their own, only one of whom had any complaints referable to swallowing. In the other four the symptoms were clearly brought out in questioning, but the comparative severity of the pain and discomfort from the cutaneous lesions caused the difficulty in swallowing to be overlooked. In 3 of the 5 cases difficulty was experienced in introducing the esophagoscope under local anesthesia. This difficulty appeared to be due in part to inability to open the mouth more than about half the normal width or to extend the tongue beyond the mucous-membrane margin of the lower lip and tightness of the skin over the jaws and neck. In addition, none of the patients were able to produce relaxation of the cricopharyngeus sphincter by swallowing. Under general anesthesia, however, the sphincter relaxed easily and the walls in that region appeared grossly normal. Some form of general anesthesia appears to be indicated for esophagoscopy in cases of this type. In all cases, the wall of the esophagus from the beginning of the middle third downward was diffusely reddened and apparently thickened, with a lessened tendency to form normal folds. In the lower third there was a diffuse layer of white exudate, that could be easily separated off, leaving a granulating base.

In summary, these authors report that the disturbances of the esophagus are characterized by

loss of peristalsis in the lower two thirds, with relaxation and mild dilatation of the lower two thirds down to the phrenic ampulla and probably son atony of the cardiac sphincter as a direct result of the sclerodermatic process; difficulty in swallowing solids or liquids, especially when in the lying position, owing to delayed emptying of the esophagus; burning pain behind the sternum about an hour after meals, which is worse on lying down and particularly on lying on the left side, probably owing to regurgitation of gastric contents into the esophagus and resulting chronic esophagitis; chronic ulceration in the lower third of the esophagus, localized chiefly in the region just above the phrenic ampulla, and probably a direct result of the esophagitis, with sclerodermatic changes as a predisposing factor; and stricture formation in the later stage limited to the region immediately above the phrenic ampulla of the esophagus. Biopsies revealed changes in the submucosa that suggested sclerodermatic change.

Esophagitis. Paul⁴⁷ has studied the roentgenologic aspects of acute and chronic esophagitis. He believes that the acute ulcerative type is most frequently associated with peptic ulcer or develops immediately following upper-abdominal operation. Anything that tends to cause relaxation of the cardia, permitting acid gastric juice to come in contact with the esophageal mucosa, may predispose to its development. Frequent vomiting is an important factor. The use of a negative-suction apparatus in itself is of questionable value but may play a part when additional causes are present. The x-ray appearances, according to Paul, consist of severe spasm of the distal part of the esophagus, loss of mucosal folds and a fine roughening of surfaces. The lesion tends to progress to a fibrous stricture. Chronic esophagitis of sufficient severity to be the cause of symptoms is uncommon. If it is present for a sufficient length of time, the x-ray findings may be those of a diffuse fibrous stricture, since the esophagus when involved by infection shows a great tendency toward the development of fibrosis. In other cases of chronic esophagitis the most striking x-ray manifestation is intermittent, diffuse spasm of the lower half or third with thickening of the mucosal folds.

Foreign body. Weaver⁴⁸ reports an interesting case in which a chicken bone remained in the esophagus for fifty-six days without perforation. This case is remarkable in view of the fact that bones are especially liable to cause esophageal perforation. The patient was a man of thirty-nine who complained of constant dull pain in the region of the epigastrium, which became worse in swallowing. The bone was removed without difficulty by esophagoscopy under local anesthesia. The postoperative course was uneventful.

Nervous disorders. Hurst⁴⁹ believes that hysterical dysphagia is rare. When it does occur, the patient

has had an incident that drew his attention to the normally automatic act of swallowing. Dysphagia may occur in various organic nervous diseases as a result of paralysis of the muscles concerned in the first and second stages of swallowing. Motor neuron disease, which includes progressive muscular atrophy and amyotrophic lateral sclerosis, may be accompanied by dysphagia if the vagal nucleus is involved in the last stages of the common form that begins in the muscles of the hands. It occurs in progressive bulbar palsy and in myasthenia gravis. Hurst believes that the most frequent nervous disorder of swallowing is achalasia, commonly known in America as cardiospasm. In the treatment of this condition he keeps mercury bougies in the esophagus for fifteen minutes just before each meal for two weeks, after which the frequency of the instrumentation is gradually decreased. The patient himself passes the bougie.

Vines and Olsen⁵⁰ report a case of cardiospasm with associated pellagra. They discuss the possible role of vitamin deficiency in cardiospasm, but in their experience favorable results were not obtained by giving vitamin B₁ to 2 patients with esophageal obstruction. When obstruction at the cardia is relieved and the patient is maintained on a normal diet, caloric deficiencies and vitamins take care of themselves.

Hiatus hernia. Vinson⁵¹ calls attention to dysphagia from hiatus hernia. In patients with the short esophageal type of diaphragmatic hernia, dysphagia results from spasm or stricture at the junction of the esophagus and the hernial sac. In those with hernia of the paraesophageal type, it results from stricture in the lower portion of the esophagus, spasm at the cardia or pressure from the herniated portion of the stomach on the lower part of the esophagus.

Extrinsic pressure as a cause of dysphagia. Tinney, Schmidt and Smith⁵² report a case of mitral stenosis in which the onset of the illness and the clinical course were dominated by difficulty in swallowing. This symptom became so severe that for nine days prior to the patient's admission to the clinic she was unable to take solid foods and was able to swallow liquids only with difficulty. On roentgenoscopic examination of the esophagus filled with barium, there was no evidence of an intrinsic lesion, but the lower third of the esophagus was displaced posteriorly and compressed by a hugely dilated left auricle. The patient received only partial relief from the dysphagia following treatment of the congestive failure.

Esophagobronchial fistula. Clerf, Cooley and O'Keefe⁵³ call attention to the four main groups of fistulas, — congenital, neoplastic, infectious and traumatic, the first two being by far the most frequent. They report 2 cases in which esophagobronchial fistula existed for nine and thirty-two months, respectively. No definite cause could be demon-

strated, although one patient had a pulmonary abscess and coughed up a mass of necrotic tissue immediately preceding the development of symptoms. There was no apparent tendency for the fistula to close after the esophagus was placed at rest. Prompt closure of the esophageal end of the fistula resulted following the esophagoscopy application of a sodium hydroxide crystal fused on a curved metal applicator and carried into the fistula for a distance of several centimeters. Both patients had subsequently been free from symptoms for more than eighteen months.

According to Haight and Towsley,⁵⁴ the surgically ideal plan for the correction of congenital atresia of the esophagus with tracheoesophageal fistula is a reconstruction of the continuity of the esophagus by an extrapleural ligation of the fistula and an end-to-end anastomosis of the esophageal segments. The first successful case of reconstruction of the esophagus by this plan is presented. The factors pertaining to operative correction of the anomaly and experiences in a series of 15 cases are discussed.

GASTROSCOPY

Normal stomach. Fitzgibbon⁵⁵ studied 40 healthy volunteers and found that 38 had mucosa within normal limits. Pigment spots and mucosal hemorrhages were not found and traumatic areas were insignificant, as contrasted with the tendency to bleed on slight trauma in gastric cases.

Technic. Moersch⁵⁶ has found that portions of the stomach that otherwise might not be adequately visualized by means of the gastroscope can often be brought into view by palpation. This method is of particular value in dealing with the antral portion of the stomach, and especially in examination of a stomach on which operation has been performed. The method is simple and causes the patient no distress. It is also of value in that it enables the examiner to determine the flexibility of the gastric mucosa. The information thus gained may be of assistance in distinguishing between a carcinomatous and an inflammatory type of infiltration.

Evaluation of gastroscopy. In a discussion on the use of the gastroscope as a supplementary aid to x-ray examination, Cohn and Levitin⁵⁷ point out that there are limitations to the x-ray diagnosis of gastric lesions that are not usually appreciated. Gastroscopy is of great assistance in clarifying certain doubtful roentgenologic findings and in differentiating others. It brings into direct vision lesions that cannot be demonstrated by x-ray. Benign ulcers have a gastroscopic appearance different from that of malignant ulcers. Carcinoma can be diagnosed and classified and the extent of involvement determined before surgery, information thus being obtained regarding its operability and prognosis. The course of a benign ulcer as regards its healing Polyps

rarely diagnosed by x-ray can be visualized by gastroscopy and their extent determined. Malignant tumors of the stomach can be differentiated from intragastric and extragastric lesions. The hypertrophic and atrophic types of gastritis can be diagnosed only by gastroscopy. Following operation, lesions such as marginal ulcers and gastritis are ordinarily diagnosed only with difficulty. The gastroscopist can diagnose both these conditions and differentiate the distorted folds of the post-operative stomach from an ulcer. The authors conclude that gastroscopy is a simple, safe procedure and is a valuable supplement to x-ray examination.

Balfour,⁵⁸ in discussing the annual report of the Mayo Clinic on surgery of the stomach and duodenum, states that gastroscopy has not only been a distinct aid in early diagnosis of cancer but has also furnished valuable information on the significance of gastritis in relation to the development of carcinoma. One may expect that the continued use of this procedure will result in a better knowledge of the factors that predispose to cancer of the stomach.

Howard⁵⁹ discusses gastroscopy and the use of the gastroscope in the military services, stating that in the diagnosis and treatment of gastric ulcers the gastroscope is of course helpful. He also states that American physicians agree that gastritis is best diagnosed by inspection of the mucosa through the gastroscope. Tumors and ulcerations, some of which escape detection by roentgen rays, are readily visualized. The easy detection of gross gastric lesions establishes the gastroscope in its merited place in the military services and does much to promote its use in civil work.

Paulson⁶⁰ reaches similar conclusions regarding the present position of gastroscopic diseases, concluding that gastroscopy is complementary to roentgen-ray examination for diagnosis. When the roentgenograms are negative and yet suspicion of abnormality persists, gastroscopy may reveal an occasional neoplasm, erosions, peptic ulceration or gastritis. These lesions may also account for otherwise unexplained hemorrhage and a duodenal-ulcer syndrome not due to duodenal ulcer. When roentgenograms are positive, gastroscopy makes possible confirmation; a nicer differentiation grossly between benign and malignant lesions; a clearer delineation of the site and extent of the lesion, which helps to determine the question of operability; the differentiation grossly of spasm and edema from the lesion itself; and the occasional detection of an associated gastritis that may account for atypical symptoms, often erroneously ascribed to a defect of the roentgenogram in the duodenal cap but due to a healed, scarred ulceration.

Gill⁶¹ in an analysis of 1000 gastroscopic examinations concludes as follows:

In gastric ulcer, the gastroscope may reveal ulcers not otherwise demonstrable, and affords proof of healing more cheaply and accurately than any other method.

In chronic gastritis, gastroscopy provides confirmation not otherwise obtainable and enables differentiation of and degree of severity, essential for satisfactory disposal of treatment. Mucosal atrophy can only be diagnosed any degree of certainty by gastroscopy.

Multiple gastric erosions are only rarely demonstrated by x-rays, but by gastroscopy lesions of some significance can be diagnosed and differentiated into the chronic acute, and disposal can be made accordingly.

In other Service cases, less numerous but no less important, gastroscopy may offer the only means of diagnosis. These include early gastric carcinoma, benign gastric tumors, postoperative dyspepsia, unexplained gastric hemorrhage and achlorhydria.

Pollard and Lopes Pontes⁶² have reached somewhat similar conclusions — namely, that gastroscopy and roentgenology, as the only direct diagnostic procedures for the detection of gastric ulcer, should be concurrently employed. Although x-ray examination reveals the lesion a little more frequently, gastroscopy appears to make it possible to discriminate between a benign and a malignant lesion in a higher proportion of cases. Both methods have their own limitations and so-called “blind spots.” Gastroscopy is the only reliable method available for the diagnosis of a primary or associated gastritis. It is also of considerable help in the recognition of certain types of localized gastritis. Roentgenologically may simulate a neoplastic formation.

Gastritis. Gray⁶³ studied the epigastric symptoms in alcoholic patients with and without gastric ulcer and found that only 7 per cent of the group of normal stomachs had symptoms referable to the gastrointestinal tract, whereas 53 per cent of patients with chronic gastritis and 60 per cent of those with severe gastritis had gastric complaints. It therefore appears from these studies that there may be a direct relation between gastritis and the incidence of symptoms in chronic alcoholic addiction.

In last year's report,¹ Benedict's⁶⁴ article on hypertrophic gastritis was reviewed. In a discussion of this paper Carey⁶⁵ stated that the picture described agreed with his own experience in that the symptoms are similar to those of ulcer. Night pain, radiation of pain were seen less frequently by Carey than by Benedict.

Spriggs and Marxer,⁶⁶ in a monograph on polyps of the stomach and polypoid gastritis, state their belief that polyps are prone to malignant degeneration. Such a change was reported in between five and one in six of the series. The diagnosis of a polyp or polyps is made by radiology and suitable cases, by gastroscopy. Polypoid gastritis usually responds to treatment, which includes dietary measures, elimination of alcohol and in some cases gastric lavage.

Kantor⁶⁷ believes that positive gastroscopic evidence of gastritis in a front-line soldier should entitle him “to every consideration and to every benefit.”

Gold⁶⁸ made a gastric study in 50 soldiers with dyspepsia and reported that gastroscopy is the only reliable method available for the study

stritis. Hemorrhage from gastritis is not a rare occurrence. Further studies, he says, are indicated regarding the incidence of gastritis in military forces, the effects of therapy and the interference of symptoms with the performance of duty.

Although it has been possible to correlate fairly accurately the gastric findings in gastritis with the post-mortem findings (Benedict and Mallory⁶⁹), it may not be so easy to account for the symptoms on a pathological basis. In this connection Ortmayer⁷⁰ pointed out that it would be difficult to correlate such symptoms with relatively minor pathologic changes, such as nonulcerating gastritis, probably because the pain threshold of the stomach is high. Even a striking lesion, such as a deep gastric ulcer, may not produce symptoms. Ulcers may be painful on one day and not at all painful on the next. It is timely to emphasize in this regard, as Renshaw⁷¹ and Wilkinson⁷² have done, that patients as a whole, not "stomachs," are being treated.

Relation of chronic gastritis to cancer of stomach. A number of observers have stated that carcinoma of the stomach does not develop on a previously healthy mucosa. Many recent reports indicate that gastric atrophy predisposes to gastric carcinoma. Among these may be mentioned that of Shapiro, Schiff, Maher and Zininger,⁷³ who found microscopic evidence of atrophic gastritis in 28 (80 per cent) of 35 cases of gastric cancer. They believe that the frequent coexistence of atrophic gastritis and gastric cancer strongly suggests a relation between them, the nature of which has yet to be determined.

Westhues,⁷⁴ on the basis of 463 resected stomachs and 40 stomachs obtained by autopsy, concludes that inflammation is not the decisive factor in the development of gastric cancer. The blastomatous gastric polyps, which are definitely precancerous in nature, are likewise not inflammatory, and cancers developing from them are not the result of inflammation. Westhues does not deny the possibility of development of cancer on the basis of gastritis.

Doehring and Eusterman⁷⁵ record the results of their observations on 40 patients with associated pernicious anemia and carcinoma of the stomach, studied at the Mayo Clinic. Of 1014 patients with pernicious anemia, 17 had carcinoma of the stomach, an incidence of 1.7 per cent, or slightly higher than that of gastric carcinoma in the general population. Carcinoma associated with pernicious anemia was found to be of a similar grade of malignancy and in the same location as carcinoma uncomplicated by pernicious anemia. Pernicious anemia usually sets in at about the age of fifty-four, while signs of cancer appear at the average age of sixty-three. Gastric carcinoma in association with pernicious anemia is becoming more frequent, probably owing to the fact that modern methods of treatment prolong the period of survival long enough for

carcinoma to set in. Achlorhydria is invariably found with pernicious anemia and usually with gastric carcinoma. The cancer usually develops in the pyloric region. It develops with less frequency in the middle third of the stomach, and is most rarely discovered in the upper third. All the cases studied were adenocarcinoma. Benign tumors or polyps develop fairly often in cases of pernicious anemia.

White⁷⁶ reports a case of pernicious anemia of long standing in which both carcinoma and tuberculosis of the stomach were found at operation. This is the tenth verified case of gastric tuberculosis encountered at the clinic and the second verified case of carcinoma and tuberculosis in the same stomach. In commenting on this case, Walters⁷⁷ remarks that in pernicious anemia it is the associated gastritis that is of concern. Gastroscopists have offered additional proof of the possible precancerous nature of gastritis. Schindler⁷⁸ has found gastric adenomas in 6 per cent of the cases of atrophic gastritis, whereas these adenomas occurred in less than 1 per cent of cases in which atrophic gastritis was not present. In addition, adenomas of the mucosa occurred in 14 per cent of cases of pernicious anemia.

Brindley, Dockerty and Gray⁷⁹ report a case of multiple carcinoma of the stomach in which examination of the resected specimen revealed four adenocarcinomas of different degrees of malignancy. In this case diffuse advanced chronic gastritis may have been a precursor of the multiple carcinomatous lesions. Credence is given to this supposition by the diffuse nature of the chronic gastritis, particularly with reference to the pronounced hyperplasia of mucous cells, and by the presence of multiple lesions of all four grades of malignancy.

Freedman, Glenn and Laipply⁸⁰ report 5 cases of atrophic gastritis simulating gastric carcinoma. They emphasize that the localized form of hypertrophic gastritis may be difficult to differentiate from carcinoma. Even gastroscopically, this differentiation cannot always be made. The diagnostic difficulties were such that carcinoma could not be excluded before an exploratory laparotomy was done. In 3 of the cases, the true nature of the lesion did not become apparent until histologic examination of the resected specimens was made. Chronic gastritis is in some cases a curable precancerous condition. Patients should be carefully followed with repeated x-ray and gastroscopic examinations.

Gastric ulcer. In a discussion of the treatment of gastric ulcer, Judd and Priestley⁸¹ point out that in certain cases all the main differential points between benign and malignant gastric ulcerations, including x-ray examination and gastroscopy, may be misleading. They believe that medical treatment of presumed gastric ulcer leaves much to be desired. The error in the preoperative diagnosis of gastric ulcer in differentiation from

cer is approximately 10 per cent. Only approximately half the cases treated medically for gastric ulcer show results that these writers consider entirely satisfactory, and about 10 per cent of them subsequently prove to have carcinoma. The results of the surgical treatment of gastric ulcer are entirely satisfactory in the majority of cases. Since the operative mortality of gastric resection in Judd and Priestley's experience has been only 2.5 per cent, they are increasingly in favor of surgical treatment.

Duodenal ulcer. Tumen and Lieberthal⁸² made gastroscopic studies of 50 patients with duodenal ulcer uncomplicated by pyloric obstruction. Of these, 33 had chronic gastritis, 1 had unclassifiable inflammatory changes and 16 had normal stomachs. The presence of gastritis did not regularly influence the clinical course of duodenal ulcer. It was impossible to postulate the presence or absence of associated gastritis on the basis of the nature of the symptoms or the character of the response to treatment.

Carcinoma. Schiff⁸³ believes that the diagnosis of gastric diseases has been greatly aided by the use of the gastroscope. In carcinoma it is helpful not only in detecting the presence of the tumor but also in determining its location, character and extent. The gastroscope is also of value in excluding the presence of cancer in suspected cases, thus frequently preventing unnecessary operation. The best results are obtained by co-ordinating the findings of gastroscopic and roentgenologic examinations.

Pack and McNeer⁸⁴ in a discussion of total gastrectomy for cancer point out the value of the esophagoscope and the gastroscope in determining the region of the growth either in the esophagus or in the stomach. If the x-ray studies show the upper third or more of the stomach to be pliable and apparently uninvolved, the flexible gastroscope may be safely introduced. It is often helpful in forming an idea concerning the amount of uninvolved stomach superior to the cancer. If the lesion extends high or if the esophagus is involved, the flexible gastroscope should not be used, because it is introduced blindly and so may traumatize the cancer and cause hemorrhage or perforation. The rigid esophagoscope of the Janeway or Jackson type is safer to employ under these circumstances, since it is passed down the esophagus under direct visual guidance at all times. Furthermore, it is possible to obtain a biopsy through this instrument. By measurement from the upper incisor teeth, one can determine the exact location of the superior margin of the cancer.

For several years partial gastrectomy by the transthoracic approach has been recognized as an outstanding contribution to gastric surgery. Sweet⁸⁵ has recently reported 7 cases of total gastrectomy by the transthoracic route. Diagnostic esophago-

scopy and gastroscopy in addition to x-ray examination may be extremely helpful in establishing the diagnosis and planning the surgical approach and in determining operability. Peritoneoscopy is also important as a means of excluding liver metastases before major surgery.

Experimental studies. Paul⁸⁶ studied 107 patients with normal gastric mucosa by gastroscopy and found that acetylsalicylic acid caused no hyperemia, edema or hemorrhage even in daily doses as high as 80 gr. The ingestion of the drug over long periods of time does not produce chronic gastritis, and the epigastric distress that sometimes occurs after the ingestion of acetylsalicylic acid may be the result of increased acid production and pylorospasm.

Layne and Carey⁸⁷ made an endoscopic study of the appearance of the gastric mucosa in the anesthetized dog, concluding as follows:

The presence of foreign material or food in the stomach causes an appearance of hyperemia with congestion and excess secretion of mucus.

Inflation flattens the mucosal folds and often brings blood vessels into view.

A diet of coarse food, such as hospital scraps, produces hyperemic, granular changes in the gastric mucosa. The gastric mucosa appears normal only when the dog is fed dog biscuits.

Atropine decreases the quantity and changes the character of gastric secretion and diminishes gastric tone.

Pilocarpine augments the amount of gastric secretion and increases gastric tone.

Benzedrine produces transient hyperemia of the gastric mucosa and decreases gastric tone slightly.

Alcohol induces generalized hyperemia of the gastric mucosa, which subsides after about five weeks. The gastric mucosa thereafter remains normal even with continued administration of alcohol.

Although it is manifestly impossible to review adequately the volume by Wolf and Wolff⁸⁸ entitled *Human Gastric Function*, this report would not be complete without mentioning the importance of their contribution. This book is based on a study of a patient with an esophageal stricture who had fed himself through a gastric fistula for forty-seven years. It is a modern continuation of the work of Beaumont, Richer and Carlson, with special reference to the significance of the psychosomatic influences on gastric functions. The character of the subject's defect offered an excellent opportunity for a prolonged close inspection of the stomach mucosa by virtue of the large size of the defect and also because of the collar of mucous membrane that lay exposed on the abdominal wall. Changes in vascularity were readily recognized by variations in the color of the mucous membrane. Accelerated blood flow in the mucosa was not merely associated with blushing of its surface; the membrane itself became wet, swollen, and turgid, and the rugae were slightly fuller and smoother. These evidences of vascular engorgement were especially obvious in the collar of mucosa exposed on the abdominal wall. During marked hyperemia, it often doubled in thickness (from 5 to 10 mm.) and its radial folds

decreased in number from twelve or thirteen to five to seven. The tissue itself under such circumstances felt succulent and boggy.

The correlation of motor activity and blood flow was demonstrated under different conditions, such as distention of the stomach, mechanical irritation, ingestion of food and swallowing. Hyperfunction of the stomach, either motor or secretory, was always accompanied by hyperemia.

Varying emotional states may be associated with profound alterations in gastric functions. In the evaluation of the effects of drugs, the prevailing affective state of the patient at the time, the circumstances surrounding the experiment and the patient's reaction to the mode and implication of the administration of the drug, as well as his reaction to its side effects, were found to be of first importance.

Changes in gastric function in reaction to various situations and accompanying emotional states are presented in detail. Observations on the collar of the mucosa were made during a discussion of appetizing foods, alarm reaction (fear), depressive thoughts, resentment, hostility, anxiety and so forth. The alterations in gastric function fell into two categories: depression of acid output, motor activity and vascularity; and acceleration of these functions. The former was associated with a reaction of flight or withdrawal from an emotionally charged situation. The latter accompanied a reaction of internal conflict, with an unfulfilled desire for aggression and fighting back. Profound and prolonged emotional disturbances of this kind were accompanied by marked and prolonged increases in gastric motility, secretion and vascularity, with reddening and engorgement of the mucous membrane, often reproducing the picture of gastritis. This picture was induced by vasomotor changes resulting in hyperemia and congestion of the mucosa. The protective power of mucus was demonstrated. An appearance simulating chronic peptic ulcer was produced by exposing a peripheral edge of the collar of mucosa continuously to the digestive action of gastric juice for four days. After the ulcer and the surrounding area had been covered with a protective petrolatum dressing, complete healing took place within three days, leaving no trace of the lesion.

The following conclusions were rendered from this study:

Undue and prolonged acceleration of acid secretion in the stomach, however provoked, resulted in hyperemia and engorgement of the mucous membrane resembling hypertrophic gastritis. The mucosa in this state was unusually susceptible to injury, and even the most trifling traumas resulted in hemorrhages and small erosions. Ordinarily the mucosa was protected from injury by an effective coating of mucus; loss of this protection in the face of minor traumas led to edema, inflammatory changes, erosions and hemorrhages. Contact of acid gastric juice with a denuded surface induced further hyperemia and acceleration of acid secretion. Prolonged

contact of acid gastric juice with a minor erosion resulted in the formation of a peptic ulcer.

PERITONEOSCOPY

Technic. Harken and Glidden⁸⁹ used transparent collapsible plastic balloons in various sizes and shapes on the cardioscope. These balloons may be applicable for peritoneoscopy, as suggested by Lamb⁹⁰ in 1941.

Cirrhosis. One of the most valuable uses of the peritoneoscope is in the study of cirrhosis of the liver and the differential diagnosis from carcinoma. In this connection it is interesting to note the frequency of cirrhosis of the liver as reported by Peller.⁹¹ This author found among the records of 6596 cases in the Bellevue Hospital, New York City, covering the period from 1934 to 1941, cirrhosis of the liver in 9 per cent of the patients over twenty years of age. Malignant tumors were found in 17 per cent of these patients.

Amberg⁹² discusses the prognosis of chronic hepatitis in children, stating that early acute hepatitis usually heals. It may progress and develop into diffuse necrosis of the liver, of which acute, subacute, subchronic and chronic forms have been distinguished. The chronic form has been interpreted as healing of the necrosis with development of cirrhosis of the liver. Cirrhosis has been defined as a progressive lesion that involves parenchymatous degeneration and fibrous and parenchymatous repair and sooner or later causes death. Unfortunately, most of the cases of chronic hepatitis that Amberg encountered were of this kind. In summary, the author reports that chronic hepatitis of children ending in cirrhosis fairly frequently extends over a period exceeding five years. It seems possible that the disease need not always end in cirrhosis but may heal. In my opinion, information regarding hepatitis and cirrhosis in children as well as in adults will be obtained by the increasing use of peritoneoscopy together with biopsy of the liver.

Kirshbaum and Shure⁹³ have reported 356 autopsy cases of alcoholic cirrhosis. The ratio of males to females was 2:1. In 42 per cent of the cases, a history of chronic alcoholism was obtained. Jaundice was present in 48 per cent, and ascites in 59 per cent. Hypertrophic livers were noted in 62 per cent, and atrophic livers in 38 per cent. All the spleens were enlarged. In 11 cases, primary carcinoma of the liver was encountered as an incidental finding.

Ascites. Meigs, Armstrong and Hamilton⁹⁴ have listed 27 cases of fibroma of the ovary with fluid in the abdomen and chest — Meigs's syndrome. The syndrome is of considerable importance, because some patients have failed to obtain proper surgical relief, whereas others, originally doomed because of a tumor considered inoperable, are now well. Undoubtedly peritoneoscopy would be of value in the diagnosis of some of these cases, especially in the differentiation of this condition and carcinoma.

nomatosis, tuberculous peritonitis, cirrhosis of the liver and other diseases in which ascites may be present.

Jaundice. White⁹⁵ has made a study of errors in the diagnosis of jaundice, limiting his paper to 175 cases that came to operation or autopsy. Peritoneoscopy was used in only a small number of cases. Over half the errors were associated with a diagnosis of cancer. Too many diagnoses of cirrhosis were made when latent cancer was present. Errors in diagnosis were made in 14 cases (8 per cent). Judging from the kind of errors reported, it is evident that a more frequent use of the peritoneoscope would have eliminated many of them.

CASE 30221

PRESENTATION OF CASE

A fifty-three-year-old housewife entered the hospital because of right-sided paralysis.

The patient was known to have had hypertension. Six or eight months before entry she was seen in the Eye and Ear Infirmary for cataract and possible separation of the left retina. The day before admission she suddenly found herself unable to speak. She then developed paralysis of the right side of the body. No other information was available.

Physical examination showed a well-developed, obese woman who was unable to speak but who appeared conscious of her surroundings. A mature cataract of the left eye was present. There was flaccid paralysis of the right leg. The right arm and hand moved only slightly. There was no facial asymmetry. The biceps, triceps, radial and ankle tendon reflexes were decreased on the right. The right patellar reflex was absent. The plantar reflexes were decreased on the right and increased on the left. There was no Kernig sign. A questionable right temporal hemianopsia was present. She could not swallow. Ophthalmologic examination showed the right fundus to have an old hemorrhage at ten o'clock. The vessels were tortuous. There was arteriovenous nicking. The left fundus could not be visualized. The heart was rapid. No other findings were recorded.

The blood pressure was 200 systolic, 125 diastolic. The temperature was 100°F., the pulse 120, and the respirations 25.

Examination of the blood showed a white-cell count of 21,400. The urine was acid, with a specific gravity of 1.024 and a + test for albumin. The sediment was negative. A blood Hinton test was negative. The nonprotein nitrogen was 27.5 mg. per 100 cc.

The patient was given 500 cc. of 5 per cent dextrose in saline intravenously the first day, and between 700 cc. and 1500 cc. of the fluid daily thereafter. She was fed by an indwelling Levine tube. On the sixth hospital day she developed diarrhea, which may have been due to an intake of 200 cc. of fluid by mouth at one time. Her condition other-

*On leave of absence.

wise remained essentially the same until the ninth hospital day, when the temperature rose to 103°F., the pulse to 136, and the respirations to 40; the blood pressure fell to 110 systolic, 88 diastolic. Examination at that time showed rapid, grunting respirations. The face was flushed. The lips and nails were cyanotic. There was herpes on the lips, and some jaundice. Many coarse, snapping rales were heard at the left base posteriorly and over the axilla, without dullness. The point of maximal cardiac impulse was felt 11 cm. to the left of the midline. The rate was rapid. The aortic second sound was equal to the pulmonic. No murmurs could be heard. The abdomen was negative. The right leg was edematous, with tenderness in the calf and a positive Homans's sign. The right superficial femoral veins were hard and tender medially above the knee.

A portable x-ray film of the chest showed questionable dullness over the left midlung field, but this could not be definitely determined. Femoral-vein ligation was deemed inadvisable. The patient was given 5 gm. of sulfadiazine intravenously on the ninth and tenth days and 2.5 gm. on the eleventh day. On the twelfth day the urinary output fell to 500 cc. on an intake of 1500 cc. The blood sulfadiazine level on the twelfth day was 40 mg. per 100 cc. The temperature came down to normal, but the urinary output remained low. Intravenous fluids, sodium lactate and high intravenous vitamins failed to affect urinary excretion. The sulfadiazine level was 9 mg. per 100 cc. on the fifteenth hospital day. On the seventeenth hospital day she became stuporous. The nonprotein nitrogen was 89 mg. per 100 cc., and the protein 6.7 gm. She became comatose and died on the eighteenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. ARTHUR WATKINS: In this case we are called on to explain a sudden right hemiplegia followed by death eighteen days later. The only information in the past history reveals a hypertension of unknown duration and a cataract of some eight months. The latter I cannot connect with the final illness. The hypertension, however, I should expect to have been directly responsible for the symptoms—the loss of speech followed by right hemiplegia within a day and unassociated with loss of consciousness. The speech loss alone might have been due to a relatively discrete lesion in the motor speech area of the cortex in the left frontal lobe in a right-handed patient. This could have been embolic or due to a small hemorrhage or thrombosis. A rather complete right hemiplegia developed within twenty-four hours, and if also due to a cortical lesion it would have involved an area sufficiently large, one would presume, to have caused loss of consciousness. It seems more likely that the hemiplegia was due to hemorrhage in the internal capsule.

I am not given sufficient data to distinguish between cortical or subcortical types of aphasia, or for speech loss due to a bulbar lesion. To connect it with the hemiplegia, the lesion could have been subcortical. There was a complete flaccid type of paralysis of the lower extremities—often seen in the early stages of hemiplegia—and nearly complete paralysis of the upper extremity. The fact that the leg was more involved than the arm also points to a subcortical lesion, as the cortical areas for speech and leg movement are quite separated.

In view of the acute onset and the known vascular disease, I can see no reason to consider brain tumor. There was no facial asymmetry, presumably, at rest. I would like to know if the movements were normal. It seems unlikely to me that they were. We are told nothing of the other cranial-nerve functions. The tendon reflexes were diminished or absent, which is in keeping with the flaccid type of paralysis. The description of the plantar reflexes is ambiguous. Without knowing whether the movement of the great toe was an inflection or an extension, I can only guess that there was a slight plantar reflex or Babinski on the right, and a quite definite one on the left. Both reflexes were therefore pathologic. If this assumption is correct, it is of great importance in localization.

The patient was unable to swallow although conscious, which is an unusual finding in hemiplegia. One immediately suspects a bulbar palsy from involvement of the nucleus of the lower cranial nerves. In such a case the lesion would have to be below the level of the seventh nerve. With complete paralysis one would expect a contralateral sensory loss. We do not know anything about the sensory findings and they would have been hard to test in this patient.

A most significant finding was the right temporal hemianopsia. This immediately locates the lesion above the brain stem, probably in the optic radiations. Hemianopsia in this area, however, would not cause loss of swallowing because of the bicortical representation of the cranial nerves. I therefore conclude that there was bilateral involvement of the cortical tracts, giving a pseudobulbar palsy, which conforms with the bilateral Babinski tests.

There was a well-marked hypertension, and vascular changes in the eye grounds, but not much evidence of renal failure as judged by subsequent urine examination, with good concentration, a + test for albumin and a negative sediment and by a normal nonprotein nitrogen. On admission, one would presume that the likeliest diagnosis was hypertension with a cerebral vascular accident—chiefly either hemorrhage or thrombosis of the left internal capsule but with some damage to the right side of the brain. There was no evidence of valvular heart disease, and there was no apparent source of emboli elsewhere in the body.

On the ninth hospital day there was a sudden change, which is about the time that we begin to

look for pulmonary complications in patients with hemiplegia who are not getting well. In this case the pulmonary embarrassment was quite severe and there was circulatory collapse as well, with a fall in blood pressure and a rapid pulse. There were rales in the left base, and dullness. The heart was not enlarged to palpation. No mention is made of pain, cough or bloody sputum, but I still suspect pulmonary infarct. Examination of the extremities then revealed an edematous right leg, with a tender calf, and a positive Homans's sign,—pain in the popliteal space on dorsiflexion of the foot,—which at once suggests phlebothrombosis. The superficial femoral veins were hard and tender. She had fever, however, and it might have been a thrombophlebitis. I suspect the pulmonary signs were due to an embolus. The portable chest plates apparently were inconclusive.

The thrombophlebitis developed in the paralyzed leg during the first week in bed. Because of the fever I presume that it was thought that the patient had an infected pulmonary embolus or a bronchopneumonia, and sulfadiazine was given. On the third day there was diminished urinary output and an extremely high blood diazine level. In spite of intravenous fluids, the urinary excretion did not increase, the patient became comatose, and the nonprotein nitrogen rose to 89 mg. per 100 cc., and nine days following the administration of the sulfadiazine the patient died. We do not know whether there was crystalluria or hematuria. She had one negative urine examination on admission, and it is possible that the renal failure was due to sulfadiazine that had precipitated and had caused renal obstruction. There is no history of pain or swelling in the kidney region. Perhaps it is unusual to have signs of renal complication develop after only three days of sulfadiazine. I have recently, however, seen reports of cases in which intravenous diazine was given routinely to surgical patients in exactly the same dosage, 43 per cent of whom developed renal complications when alkaline therapy was not given. So it seems possible that there was a renal complication due to the precipitation of sulfadiazine crystals, with obstruction. There may have also been a toxic nephritis. We do not know whether she had had sulfa drugs previously; perhaps this would have been more likely if she had had some. Another possibility is thrombosis of the renal vessels. The patient probably did have a certain amount of acidosis; she was dehydrated and had diarrhea, which makes renal complications likelier under sulfadiazine treatment.

I therefore conclude that the patient had a cerebral vascular accident which chiefly consisted of hemorrhage or thrombosis—I cannot be sure which—into the left internal capsule; there was possibly some similar involvement on the right, resulting in a pseudobulbar palsy. She had hyper-

nion, arteriosclerosis, thrombophlebitis of the right femoral vein, with pulmonary infarction, and renal obstruction due to sulfadiazine, possibly with toxic nephritis and some thrombosis of the renal vessels.

Dr. AUGUSTUS ROSE: Have you any preference between thrombosis and hemorrhage?

Dr. WATKINS: Without loss of consciousness, one would probably say that thrombosis was likelier to be the cause, particularly after such an extensive hemiplegia. But a slow type of hemorrhage might do the same thing.

Dr. WYMAN RICHARDSON: I think that Dr. Castleman should protect himself against the machinations of the Pathology Department by mentioning the fact that we had one patient who had a paraneuronal embolus to the brain through a patent foramen ovale. I am not suggesting that as the case here, but it should be mentioned.

Dr. ROSE: Occasionally, cerebral emboli occur about a patent foramen ovale and with relatively little in the way of pulmonary involvement.

Dr. BENJAMIN CASTLEMAN: Emboli from pulmonary veins?

Dr. ROSE: Yes. The leg vein is responsible for a pulmonary embolus, and another embolus is released from a thrombosed pulmonary vein in the affected area.

Dr. CASTLEMAN: I do not remember any such cases, although it would be hard to prove.

Dr. ROSE: You read about them in the textbooks.

Dr. CASTLEMAN: We had a case of cerebral embolus some time ago in which we wondered about the possibility that the embolus had arisen from a pulmonary vein close to a pneumonic area.

CLINICAL DIAGNOSES

Hypertensive heart disease.

Uremia.

Thrombophlebitis.

Right hemiplegia, with aphasia.

DR. WATKINS'S DIAGNOSES

Cerebral thrombosis or hemorrhage: large lesion in left internal capsule, small one in right internal capsule.

Hypertensive heart disease.

Thrombophlebitis of right femoral vein.

Pulmonary infarction.

Renal obstruction due to sulfadiazine crystals.

ANATOMICAL DIAGNOSES

Cerebral hemorrhage.

Pulmonary embolism, acute, massive

Bronchopneumonia.

Pulmonary congestion and edema.

Pulmonary infarct, minute.

Central congestion and necrosis of liver.

Thrombosis of right posterior tibial and popliteal veins.

Cardiac hypertrophy, hypertensive type.

Jaundice

PATHOLOGICAL DISCUSSION

Dr. CASTLEMAN: The autopsy on this patient showed a thrombus in the right posterior tibial and popliteal veins. It had in part broken off and produced a massive pulmonary embolus of the left pulmonary artery, which was probably the immediate cause of death. There were a few smaller emboli in the lungs, but only one small infarct, which measured about 2 by 1 cm. There were, however, scattered foci of bronchopneumonia and edema and congestion of the lungs. The kidneys showed a moderate degree of vascular nephritis but no evidence, so far as we could make out, of sulfonamide changes.

Dr. Kubik will describe the cerebral findings.

Dr. CHARLES S. KUBIK: There was a hemorrhage, measuring 5 cm. in diameter, in the left frontal lobe. It was farther forward than usual, destroying the head of the caudate nucleus, and displacing the internal capsule and lenticular nucleus backward. It had not ruptured into the lateral ventricle or subarachnoid space. A large part of the clot was brick red and rather firm, obviously representing old hemorrhage; another part consisted of the usual soft, gelatinous, dark-purplish clot of recent hemorrhage. Thus there were at least two episodes of bleeding. There were several small old infarcts; up to 3 or 4 mm. in diameter, in each lenticular nucleus. Such lesions are a frequent finding in longstanding hypertension, and do not, as a rule, cause obvious symptoms or abnormal neurologic signs. I do not know how to explain the left-sided extensor plantar response. There was no associated hemorrhage of the midbrain or pons.

I might add that this patient survived an unusually long time. In most cases of massive cerebral hemorrhage* death occurs in from a few hours to two or three days, though occasionally not until a week or ten days. Recovery almost never takes place. I believe that only two old cerebral hemorrhages have been found at autopsy at this hospital in the past fifteen years. Patients who survive a severe "shock" and are left with a residual hemiplegia or hemiparesis may, with rare exceptions, be assumed to have had a cerebral infarct.

Dr. WATKINS: When do you think the pulmonary embolism occurred?

Dr. CASTLEMAN: The massive one probably occurred within twenty-four hours of death. The patient may well have had one on the ninth day, associated with the fall in blood pressure and cyanosis.

*A distinction is made between cerebral hemorrhage, originating within the substance of the brain, and subarachnoid hemorrhage. In the latter condition, which usually results from a leaking aneurysm, the death rate is comparatively low, probably between 25 and 50 per cent, at the time of the first attack.

It is interesting to speculate concerning the cause of the jaundice. Ordinarily when a patient with cardiac disease develops jaundice, the first thing to be considered is infarction of the lung. The jaundice is believed to be due to the inability of a congested liver to excrete the excess bilirubin produced by the hemolysis of the red cells in the infarct. Although this patient had emboli to the lung, there was only one small infarct. It is conceivable, I suppose, that the absorption of bilirubin from the cerebral hemorrhage, which had existed for eighteen days, might have been a factor in the production of the jaundice. The liver was only moderately congested; there was some central necrosis with fatty vacuolization, but not any more than one sees in many patients without jaundice.

DR. RICHARDSON: I do not believe that absorption from the cerebral lesion was enough to have caused jaundice.

DR. CASTLEMAN: Ordinarily, I should not have thought so, but it was a large hemorrhage of eighteen days' duration.

CASE 30222

PRESENTATION OF CASE

A sixty-two-year-old housewife entered the hospital because of intermittent, severe pain in the lower part of the back of seven days' duration.

The patient was in good health until about two years before entry, when she suddenly developed severe, boring pain across the upper abdomen, with nausea and vomiting of recently ingested food. The pain gradually subsided. She was asymptomatic for two weeks, and then had a recurrence of the pain, as well as the nausea and vomiting, lasting from twelve to twenty-four hours. Similar attacks recurred every three to six weeks until three months before admission, when they entirely ceased. She had no hematemesis or tarry or bloody stools. She was markedly constipated, requiring regular catharsis. A gastrointestinal series one year and three months before entry was said to have been negative.

Four weeks prior to admission she developed slight frequency and nocturia (two to four times), with a drawing, mild, nonradiating pain just above the symphysis on urination. These symptoms persisted. There was no hematuria or pyuria. At the same time she noticed brownish irregular spots in the left upper visual field. Seven days before admission she developed an intermittent, severe, burning pain in the right costovertebral angle and low back, which persisted.

She had lost 30 pounds in two years, "most of it in the past five months." She had had considerable weakness and fatigue in the two-year period, as well as occasional cramps in the muscles of the extremities. About a year and a half before admission, in a community hospital, she had a right radical mastectomy for carcinoma of the breast. Since

then her physician had treated her with iron liver for "anemia."

Physical examination showed a somewhat undernourished woman. The right radical mastectomy scar was well healed, and there was no evidence of recurrent carcinoma in the scar or in the axilla. Some lymphedema of the right arm was present. The lungs were clear. There was a hard, lobulated mass occupying the entire lower abdomen, more pronounced on the right side and extending 5 to 7 cm. above the symphysis. It was firm, hard and lobulated, and seemed fixed to the peritoneum. Pelvic examination showed a small cervix. The uterus was normal in size and anteriorly displaced. Behind it and to the right was the described mass, which measured 8 cm. in diameter and was adherent to the vagina and partially in the pelvis.

The blood pressure was 140 systolic, 75 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood showed a red-cell count of 2,770,000, with 8.2 gm. of hemoglobin. The white-cell count was 10,000, with 84 per cent neutrophils. The urine was negative. The sedimentation rate was normal. The stools gave a + + + + guaiac test. A blood Hinton test was negative.

X-ray examination of the chest, spine and bladder, as well as the plain films of the abdomen, was negative. An intravenous pyelogram showed prompt excretion of the dye by both kidneys, outlining a nondilated pelvis, calyces and ureters on the left. The right renal pelvis and calyces were moderately dilated, and the terminal calyx was blunted. The upper half of the right ureter was visualized and showed slight dilatation. The remainder was not definitely visible below the level of the fifth lumbar vertebra, except for a small filling defect just about the ureterovesical junction. There was a pressure defect on the right side of the bladder, present, apparently due to a soft-tissue mass occupying the right side of the pelvis. A cystoscopy showed a pale bladder mucosa. In the right base the ureter was apparently pushed in by an extrinsic mass, forming a projection 4 by 5 cm. The right ureter looked normal and was easily catheterized for 15 cm., when considerable urging was required. Finally passed about half way to the kidney, the catheter drained clear urine. A retrograde pyelogram showed the right ureter to be tortuous, with a sharp angle opposite the fourth lumbar vertebra. The ureter appeared narrow just below the sacral iliac region. No calculi were visible.

The patient was given several transfusions, and on the eighth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. EDWARD HAMLIN, JR.: May we see the x-ray films?

DR. MILFORD SCHULZ: These films show slight rotation of the pelvis, calyces and upper ureter on right side. Here is the shadow of the mass occupying the right side of the pelvis, which may be responsible for the delayed emptying and abnormal filling of the kidney and ureter. There is nothing remarkable in the films of the chest except evidence of the old mastectomy.

DR. HAMLIN: We are asked to determine the nature of a mass in the abdomen. I can make little of the past history. The episodes of nausea and vomiting and of pain in the abdomen over the two years previous to entry seem rather typical of intestinal obstruction, but not much else. It is fortunate that this mass did cause pressure on the bladder and the ureter, because apparently that is the only reason the patient entered the hospital. The mass was said to occupy the entire lower abdomen but extended only 5 to 7 cm. above the umbilicus. By pelvic examination it was more on right side, and measured 8 cm. in diameter.

In attempting to determine the nature of such a mass, one can look at it from the anatomic point of view. Where could this mass have arisen? The first thing one thinks of is the uterus. This is ruled out because the pelvic examination showed a normal uterus. One next thinks of the ovary. That can be ruled out, and must be further considered. It may have been a mass attached in some way to the intestine. The positive guaiac test makes that somewhat likely. It might also have been an retroperitoneal mass of some form, lymphoma or sarcoma or something of that nature. One must think of a bone tumor, but in the absence of any evidence of bone involvement one can safely rule that out. Under the circumstances, it seems a little unusual that they did not attempt a barium enema, because it would seem that more information could have been gathered from that than from anything else.

The next question one should decide is whether this was a malignant or a benign lesion. The cachexia, the weight loss, the pronounced anemia and perhaps the stony hardness of the mass, as well as the rapidity with which the symptoms developed, all lean strongly toward a malignant tumor. The consistency of the mass is rather less in favor of the usual retroperitoneal mass than it is of tumor of some other origin, although retroperitoneal masses may be extremely hard. Therefore, I should like to consider that it was an intra-peritoneal malignant tumor and that leads us back to a tumor of the peritoneum or of the intestine. I see no way of ruling out these possibilities in or out. The positive guaiac test in the stool makes one think that it might have been a tumor that had either eroded into the intestine or arisen from the intestine, causing some bleeding. On the other hand we already know that it had had a carcinoma of the breast, and one of the rather but not too uncommon sites of metastases

of carcinoma of the breast is to the ovary. A case came to my knowledge recently of a woman with carcinoma of the breast who had had the tumor removed several years before but had developed many bone metastases and had also developed large tumors in the pelvis. It was with some interest that the physician noticed a considerable regression of the bone metastases as the tumors of the pelvis became larger, and finally at autopsy it was found that the metastases from the breast to the ovaries had completely replaced the ovaries, thus causing physiologic castration; the regression of the bone symptoms was attributed to that. So I should like to make a diagnosis of carcinoma of the breast metastasizing to the ovaries.

DR. FREDERIC B. MAYO: Could this have been a Krukenberg tumor? If not, why not?

DR. HAMLIN: I should think that it could have been.

DR. BENJAMIN CASTLEMAN: From a primary cancer of the stomach?

DR. MAYO: Yes.

DR. HAMLIN: The description of the tumor does not exactly bring a Krukenberg tumor to mind.

DR. CASTLEMAN: Most of the Krukenberg tumors are bilateral.

CLINICAL DIAGNOSIS

Carcinoma of ovary?

Carcinoma of intestine?

DR. HAMLIN'S DIAGNOSIS

Metastatic carcinoma of ovary from previous carcinoma of breast.

ANATOMICAL DIAGNOSIS

Malignant lymphoma, clasmatoeytic type, of ileum, with extension into right ovary.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: It is not surprising that Dr. Hamlin was unable to decide where to place the tumor, — ovary or intestine, — because both were involved. The primary lesion was in a loop of ileum, the whole circumference of which for a distance of 11.5 cm. was replaced by a fleshy, smooth, pinkish-gray tumor, involving the entire wall and containing numerous areas of mucosal ulceration. The tumor in the ileum was attached to and had invaded the right ovary. Together they formed the mass in the right pelvis, and this was removed.

Microscopic examination showed it to be a very cellular tumor of the malignant lymphoma group, which we classified as belonging to the clasmatoeytic or reticulum-cell sarcoma type. One would have liked to compare this tumor with that of the original breast tumor. It is conceivable that the original tumor was a lymphoma, but it is more likely that the patient had two tumors.

"EXPERT MEDICAL TESTIMONY"

A RECENT note in the April 1 issue of the *Journal of the American Medical Association* comments favorably on the attitude taken by the Minnesota State Medical Association, which three years ago appointed a committee on medical testimony to which could be referred instances in which physicians had given questionable testimony. This committee, after investigation and according to the facts, "may censure the physician, may publicize the circumstances of the particular case or may bring the matter to the attention of the state board of medical examiners for disciplinary action." A case is cited that had been investigated by the committee and referred to the board of medical

examiners; the testifying physician, having been adjudged to have given unjustified testimony, was censured.

- So-called "expert medical testimony" as given in court has long been a just cause of embarrassment to physicians, who consider much of it to be a discredit to a generally honored profession. There are no undisputed rules by which qualification as an expert can be judged, and contradictory testimony is frequently given by presumably equally qualified physicians. Furthermore, neither the medical profession nor the legal profession has interested itself in this important problem to the point of actually seeking results.

The concluding paragraph of the note in the *Journal of the American Medical Association* is worth reprinting for its uncompromising clarity.

Next to saving life and giving aid to the sick and injured no greater responsibility devolves on the medical profession than giving testimony in court or elsewhere. The right of a physician to continue in the practice of medicine is measured not only by his professional competence as a physician but also by what he says and does as a physician.

In 1936 the Council of the Massachusetts Medical Society appointed the Committee to Consider Expert Testimony, thus anticipating the action of the Minnesota State Medical Association by five years. Unfortunately, although the Minnesota committee appears to be functioning in a spirited and effective fashion, the only fruit that this appointment has borne in eight long years has been an occasional meager report of progress. Meanwhile the battles of the "experts" continue.

SECONDARY STREPTOCOCCAL WOUND INFECTION

EPIDEMICS of secondary streptococcal infections of open wounds, such as burns, or of those following so-called "clean" operations are regularly experienced, particularly during the late fall, winter and early spring, by even the most expertly conducted surgical services. The usual reaction of the surgeon is to blame the sterile materials that he had used at operation, and the bacteriological laboratory is invariably swamped with requests for the cul-

turing of instruments, catgut-and dressings. Recent investigations, however, have proved that such material is rarely, if ever, the cause of the difficulty.

Since it is well known that during the winter months the incidence of throat infections due to beta-hemolytic streptococci and the number of apparently healthy persons who are carriers of these organisms are higher than they are in the summer months, it is logical to connect this prevalence with epidemics of secondary wound infection. The organisms may be seeded in several ways — by droplet infection at the time of operation and by dust or droplet infection when dressings are changed in the ward. The persistence of beta-hemolytic streptococci, as well as that of diptheria bacilli, in dust has been demonstrated by a number of British investigators during the past five years. Garrod* has recently shown that the dust from wards where there are patients with streptococcal infections may contain these organisms in large numbers, particularly the dust near the beds of infected patients, that dust from poorly lighted areas is likelier to contain streptococci than is dust from sites on or close to windows and that virulent beta-hemolytic streptococci can persist in the dark in naturally infected dust for as long as one hundred and ninety-five days.

Prevention or elimination of secondary streptococcal wound infection calls for a meticulous routine. Efficient face masks should be worn by all members of the operating team. All personnel intimately concerned with operations or with the dressing of wounds should be tested weekly — or immediately if they develop a "cold" or sore throat — for the presence of beta-hemolytic streptococci in the nasopharynx, and they should be excused from these duties if the cultures are positive. If possible, all patients who develop streptococcal infections or who are carriers should be isolated. Ideally, the ward should be sunny. The floors should be oiled, and no sweeping or dusting should be permitted in the hour preceding the time when dressings are changed. No visitors should be admitted to the ward and activity within the ward should be restricted during the dressing period. Finally, all new dressings should be handled only with sterile instruments,

and these should be resterilized, or a new set used, for each patient. In the meantime, every surgeon should reconsider his technic from the point of view of decreasing the frequency of dressings. It has been shown, particularly in cases of burns, that, by using bulkier and more efficient dressings, they need not be changed oftener than once in two to four weeks, and in this way the danger of infection, as well as the amount of work, can be greatly reduced.

All these precautions undoubtedly cannot be taken at the present time, owing to the shortage of manpower. They offer, however, a goal to be attained, and many of them are relatively simple procedures whose adoption would accomplish much in lowering the incidence of secondary streptococcal wound infection.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

GRAVES — Word has been received of the death in the Pacific area of Lt. Commander Sidney C. Graves, U.S.N.R., formerly a prominent Boston gynecologist. His home was at 600 Brush Hill Road, Milton. He was in his forty-third year.

Dr. Graves received his degree from Harvard Medical School in 1929. He was assistant visiting surgeon at the Free Hospital for Women in Brookline and assistant in gynecology at the Harvard Medical School.

He was a fellow of the American Medical Association, a member of the American College of Surgeons, the New England Obstetrical and Gynecological Society and the Obstetrical Society of Boston and a diplomate of the American Board of Obstetrics and Gynecology.

His widow and three children survive.

HOWE — Harry N. Howe, M.D., of Greenfield, died May 11. He was in his seventy-third year.

Dr. Howe received his degree from Columbia University College of Physicians and Surgeons, New York, in 1899. He was president of the Franklin District Medical Society from 1916 to 1917. He was a member of the American Medical Association.

His widow survives.

MACDONALD — Frederick L. MacDonald, M.D., of Waltham, died May 24. He was in his sixty-sixth year.

Dr. MacDonald received his degree from the University of Vermont College of Medicine in 1907. He was the mayor of Waltham from 1934 to 1938. He was an instructor at Tufts College Medical School, on the staff of the Waltham Hospital and associated with the Massachusetts Eye and Ear Infirmary. He was a member of the American Medical Association. A daughter and a granddaughter survive.

WAR ACTIVITIES

INDUSTRIAL HYGIENE

ETHYLENE CHLOROHYDRIN POISONING

A workman in a Los Angeles manufacturing plant, while cleaning trays upon which rubber strips were stored, used a petroleum hydrocarbon solvent of the kerosene range. The supply of the solvent being temporarily exhausted, the man then used anhydrous ethylene chlorohydrin for the same purpose. He was careful to wear impervious rubber gauntlets. The room was large and well ventilated, but he was exposed to the vapors of the solvent.

When, after two hours, the workman became very ill, he was taken to the dispensary and five hours later removed to the hospital, where he died, eleven hours after he first started to use the solvent. The man was sixty-one years of age and in excellent physical health up to the time of this illness. It was found on investigation that he had been exposed to an average concentration of vapor of about 1 mg. per liter of air (305 p.p.m.).

Six white mice were exposed to a similar atmosphere and all were ill in an hour, with a downhill course after two hours. Exposure was then ended, and four hours later one of the mice died while the others were extremely ill. In twenty-four hours, the 5 mice were again normal.

Autopsy of the deceased, evaluation of the exposure and duplication of the exposure in laboratory animals with similar pathological findings, led to the conclusion that death was due to anhydrous ethylene chlorohydrin, proving that the solvent is dangerous even in relatively low vapor concentration. — Reprinted from *Industrial Hygiene News Letter* (April, 1944).

CORRESPONDENCE

PHYSICIAN NEEDED FOR BOY SCOUT CAMP

To the Editor: Rhode Island, the littlest state in the Union, has the largest Boy Scout camp in New England. Eight hundred acres are maintained by the Narragansett Council, Boy Scouts of America, as "an Adventure Land forever," tenting between six hundred and seven hundred Boy Scouts a week during July and August.

Usually, these Yankee boys are healthy but occasionally one has an accident or is "upset" in some way or another. The Camp officials are desperately in need of a resident medical officer for the summer. In normal times they employ two men on the medical staff, but this year they have no idea where to secure such assistance. They have tried all the local hospitals, all the hospitals in Greater Boston, the Army and Navy units in and around Narragansett Bay, at Camp Devens and in First and Third Naval Districts, and refugee doctors — they have left no stones unturned.

They now turn to the *Journal* to air their problem over a larger area. Is there not some man who would enjoy eight or nine weeks with kids? There is a beautiful Health Lodge with a treatment room and waiting room, as well as a ward with eight beds, a laboratory and two isolation wards, all modernly equipped. The physician's living quarters are ample for a family.

A tired civilian physician, a discharged medical officer from some branch of the service or someone else ought to be anxious to "do a good turn" for these boys. Anyone who is interested or who has a thought or suggestion is asked to communicate with Mr. H. Cushman Anthony, Narragansett Council, Boy Scouts of America, 26 Custom House Street, Providence 3, Rhode Island, or phone GASpec 9618.

DARIER'S DISEASE

To the Editor: Dr. Arthur M. Greenwood has just called to my attention an error on page 367 of the March 23 issue of the *Journal*.

The usual synonym of Darier's disease, at least in the dermatologic world, is keratosis follicularis, not pseudoxanthoma clasticum. It is true that both keratosis follicularis and pseudoxanthoma clasticum were studied by Darier. In the latter disease the name was given it by Darier in 1896, whereas keratosis follicularis was described independently in 1889 by Darier in France and Dr. J. C. White here in Boston. I have heard Dr. C. J. White say several times that the disease should have been named "White's disease" because of his father's contribution.

The description in the *Journal* fits the pseudoxanthoma elasticum all right but it is not what is commonly known as Darier's disease.

C. GUY LANF, M.D.

416 Marlborough Street
Boston 15

Dr. Lanc's letter was referred to Dr. Buck, whose reply is as follows:

To the Editor: I am forced to agree that, so far as all immediately available reference works are concerned, the eponym Darier's disease does indeed refer to a variety of keratosis follicularis.

My interest in any individual eponym begins when I hear it used for the first time. I must have been misled by hearing someone refer to a case of pseudoxanthoma clasticum as an example of Darier's disease. To that man and to myself Darier's disease meant pseudoxanthoma clasticum. Between us we must have created a new eponym.

Darier's conclusions regarding follicular keratosis may, I discover, be found in his article "De la psorospermose folliculaire végétante (On Vegetative Follicular Psorospermiosis)," which appeared in *Annales de dermatologie et de syphiligraphie* (10:597-612, 1889), with a translation from which I herewith make my apologies to the dermatologists:

There exists in man a group of cutaneous diseases that deserve the name of psorospermoses, since they result from the presence in the epidermis of parasites of the class Sporozoa . . .

This disease, which may be termed vegetative follicular psorospermiosis, should, in consideration of its etiology, be compared to Paget's disease and very probably to molluscum contagiosum.

NOTICES

DIRECTORY OF MEDICAL SPECIALISTS

The third edition of the *Directory of Medical Specialists*, listing names and biographic data of all men certified by the fifteen American boards, is to be published early in 1945. Collection of biographic data of the diplomates certified since the 1942 edition, and revision of the older listings in that volume are now going forward rapidly. Diplomates are requested to make prompt return of notices regarding their biographies as soon as possible after receiving the proper forms from the publication office.

MEDICAL SERVICE IN INDUSTRY*

DWIGHT O'HARA, M.D.†

BOSTON

THE title assigned to me suggests that there is a field in industry that medicine and surgery may enter and expand. Although this is undoubtedly true, the title might more appropriately read "Industry in Medical Service," thus indicating what is an even greater opportunity — that is, for industry to enter into and expand the field of medical service to its employees. I believe this because in the recent past and at the present time there are apparently more physicians ready and willing to enter industrial employment than there are industrial employers ready to engage them. The Committee on Industrial Health of the Massachusetts Medical Society has definitely found this to be so, even in this period of unprecedented industrial activity, for during the last year and a half it has received from physicians a dozen requests for industrial jobs for every one it has received from industrialists looking for physicians.

In this apparent discrepancy between supply and demand there are several noteworthy factors. In the first place, the supply pool, although it contains the names of several outstanding physicians and surgeons in the Commonwealth, is not a good random sample of the medical profession of the State. This is because the vigorous, well-trained physicians of today are apt to be too preoccupied with military and other services to be looking for work. In the second place, the industrialists are not generally aware of the potential usefulness of modern medical service in their business relations with their employees. They do not appreciate that the physiologic principles on which the upkeep of the human machine depends are as important as the mechanical principles on which they keep up their lathes and looms. In the third place, neither the physicians nor the industrialists generally know exactly what they are looking for, because industrial medicine is highly specialized as it has sometimes been repre-

sented to be; it needs further clarification as a specialty, if indeed it does not need to be reappraised as another form of the general practice of medicine.

There are now many types of industrial practice, and there are also many types of physicians engaged in it. They all have in common, however, certain interests that do not permit their straying as far from the fundamental principles and disciplines of medicine as many of the more highly organized specialists may. Within the last few years I have repeatedly heard candidates in Part III of the National Board Examinations request leniency or defiantly refuse to answer questions on the ground that they were not interested. This apathy was due to their intention to devote their talents to psychiatry, radiology or some other special field. They blandly assume that such interests release them from further responsibility in their wider profession. This attitude is sometimes found among third-year and fourth-year medical students, although they are usually discreet enough to keep it to themselves at that stage of their careers. The fact that such limitation of responsibility actually permits a specialist to command a larger income is one of the inconsistencies with which modern medicine has vested itself, and on account of which the cost of medical care has arisen in the large centers of population. The extent to which it has taken over the public's thinking about medicine is well known to those who have questioned the motives of the young men who now seek admission to our medical schools. In the most recent block of such young men whom I have questioned, for example, two out of twenty-one had already decided that they were going to become brain surgeons.

Of course everyone appreciates the technical advances that have paralleled this narrowing process. The primary point to be made in connection with it is that no such atrophy of medical and surgical interest or activity is compatible with the practice of industrial medicine. Certain industries have their

*Presented at the Year Session of the American College of Surgeons, Springfield, Massachusetts, March 20, 1944.
†Professor of preventive medicine, Tufts College Medical School, senior physician, Boston City Hospital, physician-in-chief, Waltham Hospital.

own peculiar and often specialized problems, but the industrial physician must be ready to be all things to all men most of the time. He must be able to do the thing that general practitioners have always done so well: to decide quickly what is important and urgent, and to use pleasing and soothing devices for the rest. Although these soothing devices have frequently been amusing, they have admirably served their purpose, which is to get the patient out of the way so that the physician can get on with his work. In large plants with well-organized medical departments the industrial physician has greater resources than has the private practitioner, but it is just as necessary for him — or for someone on his staff — to get the employee back to his job as it is for the private physician to get the patient out of his office. My first thought about medical service in industry therefore is that it should be looked on, not as a new specialty in the conventional sense, but as a new application of the general practice of medicine.

The medical department of a large plant should and usually does provide a unit with which the family physician can co-operate with complete understanding and confidence. Such co-operation between industrial and family physicians is of the utmost importance in meeting the many problems now facing industry. Among these may be mentioned the breaking in of inexperienced workers, the adjustment of handicapped people to suitable jobs, the frequency rate of accidents, absenteeism following accidents or illness and the incidence of preventable illness. The medical department is interested in all these things, but they are closely and inexorably connected with housing standards, home environments, sickness in the family, previous illnesses and incapacities of workers, shopping, amusement and transportation facilities; in short, the things with which the family physician is traditionally familiar and concerning which he is often consulted. It may thus be said that there are at least two sectors of the home front of industrial health. The medical departments of large industries are universally anxious to correlate the medical command on these sectors, and may be counted on to come more than halfway in any movement toward unification of medical outlook. Most family physicians are now convinced that this is so; if they are not, they are lacking in experience. The private physician may now be expected to work for the welfare of his patient with the medical departments of the large plants as conscientiously as he does with the public-health authorities.

In the small plants on the other hand, where the opportunity to support a medical department is usually lacking, there is not apt to be an organized interpretation of medical viewpoints for the management, and the whole subject of medical service gets off to a poor start. Traumatic surgery is generally well cared for and is well followed up by the agents

of the insurance companies. Headaches and other minor complaints may be given symptomatic treatment, but there the service rests. The problem referred to in the preceding paragraph are almost unknown because they are not recognized, whereas absenteeism, which cannot escape recognition, becomes just "one of those things." There may be a nurse or two in attendance; attending physician and surgeons are generally called when needed and are usually paid on a fee basis. Representatives of such industries probably do not attend or do not know about the periodic meetings where industrial health is discussed. Obvious hazards are promptly corrected whenever attention is drawn to them, and it is not infrequently is by a serious accident. It is true that the agents of these small plants can frequently point to excellent or even "perfect" safety scores, but such records perhaps depend on the relatively small number of employees involved or on the nonhazardous character of the particular trade that they ply. Of course many small industrial establishments are thoroughly healthful places in which to be employed. The chances are, however, that they are healthful places because someone not only has made an effort to make them so but also is attempting to keep them so.

The importance of these small plants in Massachusetts rests on the fact that their employees aggregate approximately three quarters of the men and women industrially employed within the Commonwealth. The problem is therefore large and complex, and because of the many small and diversified units into which it breaks down, it is a difficult problem. It is difficult from the employer's point of view because he cannot visualize a private medical department within his small plant any more than he can a private fire department. It is difficult from the physician's point of view because he cannot easily concentrate on the preventive aspects of an assignment that is really a very small part, and not at all an urgent one, of his total responsibility. Unless the employer or his physician can become enthusiastic about his admittedly little share of this big problem, not much progress can be made. If such progress is to be accomplished it is necessary to find an *enthusiast* — whether he is a manager, a physician, a foreman, a nurse or a janitor. He may be any intelligent person who will deliberately view a plant and ask himself about the possibilities of injury from fluids, fumes, dusts or metals. If his survey raises any suspicion that the worker's health is being undermined, the hunt is on. The physician who has this enthusiasm and interest is the ideal hunter. If he has practiced medicine successfully he will enjoy in a greater degree than do others, the confidence of those who know him, and as a physician he will have a natural knowledge of physiology on which he may build and through which he may be able to answer many primary questions. Indeed, the general practitioner may have

an approach that gives him fundamental advantages over other persons, even over specially trained industrial hygienists. No person who is not enthusiastic about the idea as a whole, however, will be likely to succeed in producing results.

There is a most useful group of people who are now organized and available in almost every community — the people who variously call themselves district, visiting or community-health nurses. They are in a particularly strategic position to promote industrial health in small plants, especially if the casually employed plant physician will give them the "green light." They are not expensive or intrusive; they are familiar and in daily touch with public-health regulations; they enjoy the confidence of the people and of the medical profession; a given slight encouragement by a few small plants they can afford to assign one of their staff to inform herself specifically in the principles of industrial hygiene. I have been much interested in watching the evolution of such a district nursing group in a city of 40,000 population with which I am familiar. They have successively trained different persons on their staff, so that in addition to what they call a "diabetic nurse" and a nutritionist they now have two members who have been trained in the elements of industrial hygiene. One of these nurses recently learned, almost surreptitiously, of a skin blemish that on tactful investigation was found to be part of a widespread epidemic of cutting-oil dermatitis among a group of women machinists whose thighs were exposed through absorbent overalls. Because their hands and faces were not involved these workers had not complained and had kept the condition of their legs to themselves. Medical advice led to proper protection and remedial measures, which promptly ended the trouble.

The nurse has traditionally held an intermediary position between the physician and his clientele; she can make or ruin him professionally almost as easily as his wife can make or ruin him socially. The nurse can as readily promote or neutralize industrial health; in the large and medium-sized plants she has already demonstrated her great value and has successfully promoted the health of the workers in many ways. In the small plants she must, however, be alert and resourceful; she must have a broad horizon, an active imagination and vigor if she is to keep herself from settling back into a soft corner,

where she has to knit and read while she waits for the opportunity to paint iodine on a hangnail. It seems that the small plant must be guarded against this leisurely sort of nursing routine, and for this reason the district nursing type of setup is extremely appealing. These district nurses have the added advantage that they are in close touch with the homes, the schools and the families of the men and women with whom they work. It is again the same advantage that the general practitioner enjoys — that of not being limited by the fence that surrounds the plant. The scope of industrial medicine, like that of preventive medicine, can have no such limit.

It is doubtful whether the managements of three or four different small plants could agree for long on the terms under which they might jointly employ an industrial nurse, but there is no doubt at all that they could all deal satisfactorily with an independent district-nursing organization. The independent organization, by working on an hourly basis, can adjust the service to the times that will meet the needs of each plant, thus relieving the plant managers of the vexing problem of deciding whether they should employ their nurses on full-time, half-time or quarter-time periods. It should appeal to the economic sense of businessmen to be able to buy only what they need. This is the best solution I have yet seen in operation for giving to small and moderate-sized industrial enterprises something that they can afford and that their employees are entitled to.

SUMMARY

Although single industries may expose their workers to special hazards, the practice of industrial medicine is a form of the general practice of medicine.

At the present time medical service is well organized in many of the large plants. Private practitioners should co-operate with the medical authorities of these plants as they do with public-health authorities.

Medical service in the small plants in Massachusetts is not well developed. It has been and can be developed by district-nursing groups in an efficient and economic manner. Private practitioners may well take the lead in this matter.

THE CLINICAL SIGNIFICANCE OF BACTERIURIA IN PATIENTS
WITH SPINAL-CORD INJURIES*

DANIEL BADAL, M.D.,† DONALD MUNRO, M.D.,‡ AND MARION E. LAMB§

BOSTON

ALTHOUGH it has long been recognized that infection of the genitourinary tract is one of the most prolific causes of death and disability in patients with spinal-cord injuries, we have been unable to find any data on the incidence of the different types of infecting agents, and in particular could discover nothing in regard to the clinical significance of a bacteriuria and the relation its presence has in such cases to the production of symptoms of cystitis, ureteritis or pyelitis. In the course of establishing the effectiveness of tidal drainage as a means of controlling infection of the genitourinary tract, it shortly became apparent that an effort must be made to differentiate a bacteriuria and an active infection of the tract. As integral parts of this problem the effectiveness of various urinary antiseptics had to be determined, the influence of an indwelling catheter on the prolongation of bacteriuria ascertained, the incidence of bacteriuria in normal uncatheterized persons settled, and finally a method developed by which the urine could be conveniently and accurately cultured and at the same time overgrowth of any one contaminant sufficient to mask the presence of others prevented. This paper presents our experience with these various problems.

METHOD OF CULTURE

It was obvious that before any such investigation could be undertaken a proper method of culture must be developed. Moreover, to be significant the urine to be cultured had to be bladder urine uncontaminated by passage through the urethra. It was evident that to meet this requirement catheterization would be necessary. Moreover, some method must be adopted to minimize the effect of the contamination of the bladder urine by the transference of urethral bacteria on the catheter as it was inserted. The method that was finally evolved and that has proved satisfactory for the last eight years follows. It is reliable, dependable and accurate. The cultured plates are easy to read and are not overgrown by the more prolific bacteria.

After washing the external meatus with soap and water a new sterilized catheter is inserted in the bladder. The use of a new catheter decreases the chances of contamination slightly and is preferable

but not essential. Catheters that have been in use so long a time as to have become encrusted with urinary salts should not be employed. The bladder is emptied and irrigated gently with a sterile 0.5 per cent solution of acetic acid, which is then removed. The catheter is fastened in place and clamped off, and the bladder is allowed to fill from the kidneys for two hours. At the end of this time the catheter is opened and 10 cc. of urine is allowed to wash through the catheter, which is then closed off again. The outer wall of the catheter is sterilized by painting the area between the meatus and the clamp with full-strength tincture of iodine. This is allowed to dry, a sterile hypodermic needle attached to a sterile syringe is plunged through this area into the lumen of the catheter, and urine is withdrawn therefrom into the syringe. One drop of this urine is placed on a blood agar plate and spread over half the plate with a sterile loop. The loop is then resterilized and the other half of the plate is subcultured from the urine that has been spread over the first half. The ideal way is to plate the urine at the patient's bed with due care to prevent contamination, but if this cannot be done the syringe and needle should be carried at once to the bacteriological laboratory and the plating carried out there. Any delay in making the culture alters the relative amounts of the various bacteria in the urine and leads to confusing overgrowths on the plate. An eosin-methylene blue plate and blood broth may be used. We have not made anaerobic cultures.

Urine cultures have been made by this method on 53 out of 169 cases with all levels of spinal-cord and cauda-equina injuries. Five hundred and seventy-eight cultures have been examined (Table 1). Table 2 shows the number of cultures per patient, and Table 3 gives certain data relative to the

first culture made and to cultures made within twenty-four and forty-eight hours after the injury; as well as the total number of various bacteria

grouped according to the class of case. The first culture made in each patient showed a single type of organism in only 20 cases. There was no growth in 27. Table 4 shows the total number of cases in which the different kinds of bacteria were cultured. It is apparent that *Proteus vulgaris*, *Esche-*

there were too many uncontrollable factors to make them suitable subjects. In addition to plating 1 drop of urine, cultures in blood broth were made of 1 cc. and 5 cc. of urine in order not to miss the more dilute concentrations of bacteria. Growth on the plates was reported as follows:

TABLE 2. Number of Urinary Cultures Per Patient.

Esche- coli, alpha-hemolytic streptococci, enterococci and staphylococci are the significant bacteria. It should also be noted that although proteus and colon bacilli predominated in the cultures, alpha-hemolytic streptococci and enterococci were present at one time or another in the bladder of as many patients as showed the former two bacteria. It also appears probable in the light of this

four to ten colonies, +, the most profuse growth +++++, with ++ and +++ in intermediate types of growth. All the cases that showed positive cultures in 1 drop of urine also showed positive cultures in 1-cc. and 5-cc. amounts. Diphtheroids were grown six times in 5 cc. of urine only. They appeared alone five times and in combination with *Staphylococcus albus* once. When

and the figures cited above that in this type of case *Pseudomonas pyocyaneus*, nonhemolyzing streptococci, a miscellaneous group of bacteria and possibly diphtheroids may well be contaminants of the various cultures rather than true inhabitants of the urethra or the bladder urine.

CONTROLS

In an endeavor to determine the incidence of bacteriuria among normal persons, 50 men were selected for urinary culture (Table 5). Before selection a careful history was taken and a thorough physical examination was made. Only those patients who had a history of never having had any genitourinary disease or injury and whose condition at the time of examination had no relation to the genitourinary tract were included. No women were examined because it was believed that

they appeared alone there was no other growth in any dilution. *Staph. albus* was grown alone once and in combination with an alpha-hemolytic streptococcus once; and an alpha-hemolytic streptococcus was grown alone twice, but in 1 cc. and 5 cc. of urine only. When present at all, *Staph. albus* showed only 1 colony per plate three out of four times and a + growth once. *Esch. coli* was present in ++ amount once, as were alpha-hemolytic streptococci in + amount; *Staph. citreus* showed only one colony per plate once.

Clinical evidence of bacteriuria, with or without evidence of infection in the form of a rise in temperature and leukocytes in the urine, was investigated in this control group. No patient had an abnormal temperature. In looking for leukocytes 10 cc. of urine was collected at the time of the culture and examined in a fresh state. The specimen was slowly centrifuged for two minutes and the un-

point where a dangerous illness developed. In certain cases the bacteria could not be killed even *in vitro* by the drugs. Salvarsan was tried intravenously in another group of patients suffering from what were believed from the descriptions in the literature to be susceptible infections but was a failure in every case. Urotropin by mouth was not tried. Hand irrigation of the bladder at four-to-twelve hour intervals was also practiced using suspensions of sulfanilamide, sulfathiazole and sulfadiazine, and 1:500 and 1:300 dilutions of an aqueous iodine solution (Lugol's). The sulfonamides were complete failures. If the iodine solution was instilled into the bladder and left there for five minutes, it could be demonstrated that the iodine was all absorbed, and indeed in one case symptoms of iodism appeared. The urine, however, was not sterilized. Daily irrigations were no more successful. By this time certain of the earlier patients who had had pyelitis and bacteriuria during their stay in the hospital but whose bladders had returned to normal before their discharge had had urine cultures made on them at various intervals after permanent removal of the inlying catheter. In every case except 2, and in spite of the failure of previous medication, these patients' urines became sterile without any further treatment other than the removal of the catheter, and all remained so. Such end results have been reported elsewhere by one of us,¹ and are introduced here only to emphasize the failure of these attempts to sterilize the urine when the inlying catheter remains in the bladder.

At about the time of these experiments MacNeill and Bowler³ published their modification of the tidal-drainage apparatus. This provided efficient bladder irrigation. It was also drawn to our attention that potassium permanganate—which was the irrigating solution then in use—was alkaline and therefore not suitable for control of the bacteria that flourished in an alkaline urine. The tidal-drainage apparatus was therefore redesigned and a 0.5 per cent solution of acetic acid was substituted for the permanganate. The culturable bacteria were reduced in numbers, and with a stronger solution of acetic acid the urine could be rendered mildly acid, but it could not be sterilized. Certain urines that tended to throw down phosphate crystals could be made clearer, but the bacteria were still present and remained until the inlying catheter was withdrawn, after which, if the bladder was either normal or of reflex type, they disappeared without anything further being done. Before this conclusion was reached, aqueous iodine, all strengths of acetic acid solution up to 5 per cent and suspensions of sulfathiazole and sulfadiazine had been used without any effect except to produce salivation and mild iodism in 2 patients. No urines were sterilized by any of these solutions. Clinical evidence of pyelitis and cystitis dropped

off sharply, however, because of the greater efficiency of the tidal-drainage apparatus. The most significant findings of all this investigation, so far as the bacteriology was concerned, were two. One was that male urethras that are deprived by presence of an inlying catheter of the irrigation and mechanical cleansing they ordinarily receive whenever the bladder is normally emptied are a constant source, particularly at every fresh catheterization, of reinfection of the bladder urine. The other is that the tidal-drainage apparatus itself reinfected the bladder urine if it is not completely dismantled, cleaned and sterilized once a week.

For the last two years no attempt has been made in this clinic to alter the bacteriuria that is always present in association with the use of tidal drainage in patients with a spinal-cord injury. All one of such patients who have left the hospital during this period have had sterile urines provided the indwelling catheter is no longer in place. The genitourinary tracts have been otherwise normal and the function has been appropriate to the lesion in every case. With the use of the present day tidal-drainage apparatus as further modified by Stewart⁴ as well as by Cone and Bridgers, insistence on weekly cystometrograms, the use of small catheters and the avoidance of all instrumentation of the bladder, the occurrence of urethritis, ureteritis and cystitis has ceased to be a significant problem except in the presence of a bladder stone. When any such infections occurred, they have been brought under control in every case without the use of drugs by mouth and by the proper adjustment of the tidal-drainage apparatus and the administration of large quantities (5000 cc. every twenty-four hours) of fluid by mouth, through a stomach tube or intravenously. A renal stone developed in 1 case, a bladder stone in 2. All these stones were removed surgically. We are therefore convinced that administration of the sulfonamides or any of the other so-called "urinary antiseptics" by mouth as an irrigating fluid in the bladder cannot control the bacteriuria that always accompanies an inlying catheter as used in the treatment of the tidal drainage of patients with spinal-cord injury. Moreover, we have satisfied ourselves that bacteriuria is harmless and disappears with permanent withdrawal of the catheter, and that pyelitis, ureteritis or cystitis does develop in the course of treating such a patient, such an infection promptly clears up following either the removal of any stone that may be present or adjustment of the apparatus and the ingestion of adequate fluids.

SUMMARY AND CONCLUSIONS

A satisfactory method of making a urine culture is described.

asymptomatic bacteriuria may be present in a healthy, active person without his knowledge and without the production of symptoms.

The presence of an indwelling urethral catheter is always accompanied by bacteriuria by the end of twenty-two hours.

Patients with spinal-cord injuries who are treated with tidal drainage have an alkaline urine that is acidified.

Isolation of the urinary tract as distinct from bacteriuria in such patients is best recognized by clinical signs. These are the onset and progress of the disease, the study of the urine and a sudden change in the temperature, usually accompanied by a fever.

Our experience with sterilization of the urine in the case of an indwelling catheter used as part of the drainage apparatus in treating patients with spinal-cord injuries has been impossible except by withdrawal of the catheter, and is unnecessary provided the latest-type apparatus is used and is properly adjusted to the bladder it is serving.

Isolation of the urinary tract as evidenced by the clinical signs and signs of pyelitis, ureteritis and bacteriuria in a patient with a spinal-cord injury who is treated by tidal drainage is best controlled by readjustment of the apparatus, bed rest and administration of large amounts of fluid, usually by mouth.

Patients who have had a spinal-cord injury and recover to be discharged from the hospital can expect to have a normal genitourinary tract with normal function and without bacteriuria unless they have had a transection of the cord, a renal or bladder stone, a draining periurethral abscess or a lesion that has produced permanent physiologic or anatomic denervation of the bladder.

If such a patient has had a transected spinal cord, he can expect a reflex bladder without bacteriuria and without the need for an indwelling catheter under ordinary circumstances.

If such a patient has had a physiologic or anatomic denervation of the bladder as the result of injury, he can expect a shrunken, useless bladder with bacteriuria and probably recurrent bouts of pyelitis.

TUBERCULOSIS OF THE LOWER LOBE

EMIL Z. OSSEN, M.D.*

QUINCY, MASSACHUSETTS

THE lower lobe of the lung as the origin of reinfection tuberculosis has been the subject of discussion from time to time in the past. It has never been treated as an entity in textbooks and in all probability does not deserve to be. However, because of its comparative infrequency in routine admissions to sanatoriums and consequently its much rarer appearance in general practice, there has been a tendency on the part of physicians to ignore its existence. Within the last few years three noteworthy clinical studies have been reported, calling attention once again to this syndrome, its possible pathogenesis and the other factors that are peculiar to manifest tuberculous disease in this area.¹⁻³

True basal lesions—that is, those found just above the diaphragm—are extremely rare, but tuberculous lesions located in the upper portion of the lower lobe are not infrequently observed. In fact, as far back as 1888 the latter location was

commented on by Fowler,⁴ who wrote that the apex of the lower lobe was second in vulnerability to the extreme apex itself. Since then others have shown that this site is not an unusual location for early cavities.

A study of the literature shows that the reported incidence of adult-type or reinfection-type tuberculosis of the lower lobe varies considerably. It ranges from 0.003 per cent of sanatorium admissions, as recorded by Reisner,¹ to 5.6 per cent for men and 10.0 per cent for women, as reported by Viswanathan.⁵ In this country it varies between 0.5 and 4.0 per cent of sanatorium admissions, with the latter figure representative of the incidence in female patients.⁶⁻¹¹ It is generally accepted that the frequency is greater among women than among men, on the right side as compared with the left and in the younger age groups as compared with the older ones,³ and that race and nationality seem to play no part.

The material available for this report was accumulated over a six-year period (1931 to 1937) in which

*Assistant physician, Beth Israel Hospital, Boston, member of Courtesy Staff, Quincy City Hospital, associate member of staff, Milton Hospital.

some 700 admissions occurred at the Norfolk County Sanatorium. The 14 cases represent 2 per cent of all admissions during this period.

In most of the available reports the authors state that their series consist of cases in which the manifest clinical tuberculosis is believed to have begun in the lower lobe. Many writers add that some of these cases have small nodular or fibrotic lesions in one of the apices, but because the presenting and predominant disease is in the lower lobe, they consider the other lesions inactive or obsolete and hence of no consequence. The material gathered for this report deals with the same type of case, but the presence of contralateral or ipsilateral involvement outside the lower lobe has been recognized

in one or the other apex. Although this is a small series and thus not properly suited for statistical use, an analysis of these two groups presents data that are deemed worthy of consideration.

Three cases were not included in this series. One was that of a granite worker over sixty years of age who had unquestionable evidence of silicosis and in whom a tuberculous cavity was first noted in the left lower lobe. In a series of over 75 cases of silicosis and tuberculosis there were 3 in which the tuberculous cavity of infiltrate seemed to begin in the right middle lobe. In such cases, where two diseases resemble each other closely, it is difficult to determine in which locality the tuberculous process first becomes clinically manifest, although the major

TABLE 1. Summary of Data.

CASE No.	SEX	AGE yr.	CONTACT WITH TUBERCULOSIS	SIDE AFFECTED	REACTION OF SPUTUM	TYPE OF ONSET	COMPLICATION	TREATMENT	RESULT (1943)
PURE TYPE									
1	M	19	Mother and 2 siblings	Left	Positive	Acute	None	Pneumothorax	Disease arrested (10 yr.)
2	F	16	Father	Right	Positive	Acute	None	Pneumothorax and phrenicectomy	Disease arrested (3 yr.)
3	F	17	Brother	Left	Positive	Acute	None	Pneumothorax	Disease arrested (3 yr.)
4	F	19	Mother	Right	Positive (gastric lavage)	Chronic	None	Pneumothorax and phrenicectomy	Disease arrested (4 yr.)
5	F	17	Sister	Right	Positive	Acute	Spread to opposite side	Pneumothorax and phrenicectomy	Patient failing; positive sputum.
6	F	19	Sister	Left	Positive	Acute	None	Bed rest	Disease arrested
7	M	23	None elicited	Right	Positive	Acute	None	Pneumothorax	Disease arrested
8	F	22	Brother	Right	Positive	Acute	Tuberculosis, enteritis	Pneumothorax	Death
IMPURE TYPE									
9	F	29		Right	Positive	Chronic	None	Pneumothorax and thoracoplasty	Disease arrested
10	F	33		Right	Positive	Chronic	None	Phrenicectomy and pneumothorax	Patient refused thoracoplasty; positive sputum.
11	F	37		Right	Positive	Chronic	None	Pneumothorax and pneumolysis	Disease arrested
12	F	26		Right	Positive	Chronic	None	Pneumothorax and phrenicectomy	Disease present; negative sputum.
13	F	23		Right	Positive	Chronic	None	Pneumothorax	Disease arrested; recurrence on opposite side (6 yr. later)
14	F	37		Right	Positive	Chronic	None	Pneumothorax and pneumolysis	Negative sputum after pneumothorax

and has been made the basis for dividing the cases into two groups (Table 1). A new classification is not offered, but for the purposes of study the cases have been arbitrarily divided into these two groups and the terms described below have been applied. Furthermore, it is fully realized that x-ray studies are too crude for absolute differentiation of the two groups, but they are justified by the results of the analysis. By making this distinction, a unique approach not hitherto reported is attempted and the results of analysis seem to warrant reporting.

In the first group, designated as "pure," are placed 8 cases in which the x-ray appearance of the lesion was limited entirely to the lower lobe with no visible evidence of obsolete, nodular or fibrotic lesions elsewhere in the lungs. In the second group, designated as "impure," are placed 6 cases in which in addition to the predominant lower-lobe lesions nodular or fibrotic disease, such as described above, was found

of silicotic patients develop phthisis in the upper lobes in the same proportion as do those with tuberculosis uncomplicated by silicosis.

The second case was that of a seventy-five-year-old woman who had bronchiectasis of the lower lobe of twenty years' duration. A sputum positive for tubercle bacilli was demonstrated once in a series of more than fifty examinations. After death from congestive heart failure, autopsy disclosed considerable bronchiectasis of the right lower lobe, a just beyond the wall of one of the smaller bronchi a caseous tubercle 1 cm. in diameter was noted. It is difficult to classify this case. The patient may not have active tuberculosis in the accepted sense. A logical explanation is that before death there was softening of an old tuberculous focus, perhaps owing to a bronchiectatic abscess or low-grade pneumonia with consequent shedding of a few bacilli in the sputum.

The third case was that of a male diabetic patient forty-four years of age who had a small lesion in the apex on the right side. Since the evidence for a lesion of the middle or lower lobe was not clear, this case has been omitted.

SYMPTOMATOLOGY

A study of the onset reveals that the cases in the present series are roughly divided into the acute and chronic types. The former, generally associated with the pure type, simulated the onset of pneumonia, whereas the latter was common to the impure type and was most frequently diagnosed as bronchitis or bronchiectasis. Of themselves, no symptoms were found to be pathognomonic of lower-lobe tuberculosis. Sokoloff,¹² however, points out that in his series a distinction in the symptomatology could be noted by early onset of night sweats, which in addition usually affected a limited part of the body—that is, the neck, shoulders or head. He also reported an afternoon fatigue that disappeared with sleep.

Analysis of this series (Table 2), shows distinct differences with respect to age, sex, side affected and type of onset. As regards the history of tuber-

TABLE 2. *Analysis of Series.*

Factor	Pure Type	Impure Type
Sex	6 female; 2 males	6 females
Age	16-33 yr., average 19 yr.	23-37 yr., average 31 yr.
Side affected	5 right; 3 left	6 right
Tubercle bacilli in sputum	All	All
Type of onset	7 acute; 1 chronic	All chronic

culous contact, in the pure group there was a strong family history of tuberculosis and intimate contact, suggesting that these patients had received large and frequent dosages of tubercle bacilli in the past. The majority of them had been separated from their original contacts for many years. This is a not infrequent history in tuberculosis of the upper lobe. In the impure group there was no history of tuberculosis contact, familial or otherwise. This suggests that a small apical lesion is acquired after many years of sporadic or chance infection and becomes arrested or quiescent. At some time later in life, perhaps during an intercurrent respiratory infection, the bacilli are set free from this old focus, drain down the right bronchus and are localized in the area of vulnerability (described below), where they thrive and ultimately cause caseation, slough and cavitation. With the development of the cavity, the symptoms bring the lesion to the attention of the patient, who seeks medical advice. The impure type is probably not true lower-lobe disease but what could be more properly termed metastatic lower-lobe tuberculosis. For this group a hypothesis has been advanced to explain the predisposition for the right side and the lower lobe.

It is difficult to explain the numerical preponderance of female over male cases in this and other

reported studies. Available statistics reveal that more girls than boys develop manifest tuberculosis during adolescence. Thus, one expects a greater percentage of teen-age girls than of teen-age boys in a sanatorium, and hence a greater opportunity for encountering lower-lobe disease among females than among males. This does not, however, explain why there are not more cases of lower-lobe tuberculosis among men between twenty-five and thirty-five years of age, in which age group the male incidence of tuberculosis is at its highest. Some other explanation than that of age must be sought to explain the localization of basal tuberculosis.

The right side was involved in all the impure cases and in 5 (62 per cent) of the 8 pure cases. This finding is in accord with that of most writers. Eleven of the 12 women had the lesion on the right; in both the men they were equally distributed.

PATHOGENESIS

Two mechanisms regarding the pathogenesis of the pure group suggest themselves. According to the first of these, the caseous-pneumonic lesion is the result of a bronchiogenic or hematogenous spread from the lymph-node component of the primary infection and the lesion, which is usually situated in the upper lobes, has by chance involved the lower lobe. According to the second mechanism, there is direct extension from the parenchymal component of the primary complex, which is oftenest found in the lower lobe on the right side. Sweany¹³ has shown that such a process actually occurs in adolescents or young adults who acquire their primary infection during adolescence. The course in these cases is, however, generally rapid and fulminating. The present series includes no case of this type, with the possible exception of Case 8, in which death from tuberculous enteritis occurred.

The impure cases appear to offer more consistent findings. The universal localization in the lower lobe on the right side in women is the outstanding finding. This is best explained on the basis of a theory developed by Reisser.¹ This theory presupposes an area of marked limitation of motion in the lung, which Tendeloo and Macklin¹⁴ have termed the superoretrocardiac area. Roughly, the area is paravertebral and corresponds to the usual location of the apex of the lower lobe. This theory has been worked out in the following manner. The diaphragm plays an important role in the expansion of the lower lobe and the posterior portion of the upper lobe, whereas the costal movements are largely responsible for the expansion of the middle lobe and the anterior part of the upper lobe. In general, therefore, it can be postulated that the effectiveness of diaphragmatic action progressively decreases posteriorly and superiorly and that minimal action is obtained at the area corresponding to the apex of the lower lobe. Men are known to be predominately diaphragmatic breathers,

whereas women are costal breathers; consequently, in the latter normal respiration demands little diaphragmatic excursion, with the result that the lower lobe, particularly its upper portion, is poorly ventilated. One can therefore account for a region in the lung that is relatively inert, poorly aerated and in all probability vulnerable to infection. Furthermore, the right side of the diaphragm is more elevated than the left, owing to the underlying liver, and is in consequence liable to a somewhat lessened excursion. This is particularly so in women, as shown by fluoroscopic examinations of the chest. Reisner¹ adds that the right main bronchus comes off the trachea at a lower angle than does the left main bronchus, and in consequence any spreading bronchiogenic infection more naturally drains to the right than to the left side, thereby coming to rest in this vulnerable area. Since the majority of writers have noted the marked preponderance of tuberculosis in the right lower lobe in women, this theory seems to explain their predilection for lower-lobe disease as compared to that of men.

Medlar and Sasano,¹⁵ working with various strains of tubercle bacilli inoculated intravenously in vaccinated rabbits, noted that cavitating lesions were localized in the dorsal and posterior parts of the lung, which are in the superior portion of the rabbit in the usual position of rest, whereas the lesions in the anterior and ventral portion had cleared. Further experiments, in which the rabbits could be kept in a given position for over half the day, over a long period of time, resulted in earlier death, but examinations revealed a localization of the tuberculosis in the highest part of the lung. These authors note an analogy between this tendency to superior localization and the apical or subapical involvement in the human lung.

Medlar and Sasano frankly admit they do not know why the lesions localized as they did, since there is admittedly no peculiar anatomic structure of the lung that lends itself to progressive infection. Also, an alteration of the lung occurs with a change of posture, since emphysema develops in the rabbit's lungs if it is kept in an upright position over a given period of time.

From these studies, it was obvious that neither inhalation (the natural route) nor allergy with subsequent reinfection is of prime importance in the determination of the localization of the progressive cavitating tuberculous lesion.

It is common knowledge that a considerable proportion of spreads to the lower two thirds of the human lung resolve completely, and when they do not, this is probably due to an overwhelming infection or to extreme virulence of the germ. A progressive basilar infection is therefore always of grave import, especially in the absence of apical or subapical involvement. Medlar and Sasano conclude that higher portions of the lung field are less resistant to tuberculous infection than are the lower

portions, and that to obtain localizing cavitating lesions it is necessary to have a certain balance between the virulence and dosage of the tubercle bacilli and the resistance of the host, together with a localizing of the tubercle bacilli in certain areas of lung parenchyma; that allergy alters the tissues only so far as the response is more vigorous or prompt; and that this alteration is but one factor that may lead to a localizing cavitating lesion. The factor of greatest importance seems to be the establishment of a certain balance between host and parasite.

DIAGNOSIS

Lateral as well as conventional x-ray films are necessary before a topographical diagnosis of lower-lobe disease can be entertained. The diagnosis of tuberculosis should not be made unless a positive sputum (or gastric lavage) is obtained. As will be noted, this was demonstrated in every case in the series. This does not mean that a positive sputum will be obtained in every case of lower-lobe tuberculosis when first seen. On the contrary, it may not be possible to obtain one in the first few days or even weeks after onset, especially in the pure type. This is also true of the proliferative or exudative type, which resembles a low-grade pneumonitis persisting over four to six weeks, and in which a strong contact history of tuberculosis can be elicited. In such cases it may take months of sputum and gastric examinations before tubercle bacilli are found.^{16,17} Thus, roentgenologically speaking, lower-lobe lesions differ from apical ones in that in the latter a diagnosis of tuberculosis can often be made without a positive sputum, whereas in the former a positive sputum is essential.

In the differential diagnosis another lesion that may cause confusion is an active apical tuberculous lesion in association with a unilateral or bilateral basilar nonspecific bronchiectasis. Although this is a rare combination, it is important that the distinction be made, since the principles of treatment for each condition differ markedly. Bronchography and if necessary bronchoscopy should be carried out if the double condition is suspected. A lead to the diagnosis is the copious quantity of sputum, out of all proportion to the size and number of tuberculous cavities present, as well as the small degree of parenchymal involvement in the face of a positive sputum.

Of particular interest at present are the atypical pneumonias, most frequently basilar in distribution and requiring three to six weeks for resolution. They are, however, usually migratory and bilateral, which differentiates them from tuberculosis by the changing signs and the sequence of events. Serial chest roentgenograms soon rule out this condition. In fact, it cannot be emphasized enough that a single positive x-ray film of the chest is often not only misleading but dangerous.¹⁸ Besides the atypical

pneumonias, one must bear in mind the delayed type of resolving lobar pneumonia due to a pneumococcus, particularly since the right lower lobe is often involved.¹⁹ The time interval required for resolution and the absence of residue differentiate these two conditions. It also helps to differentiate basal pneumonias complicating minimal or obsolete apical tuberculosis from tuberculous spreads.

Lung abscess should not be confused with lower-lobe tuberculosis since most of these abscesses follow surgical procedures, and the others can be ruled out by repeated sputum examinations. The sudden onset, the typical pus and the physical signs also aid in the differentiation.

As for the pulmonary mycoses, coccidioidal infections are a problem peculiar to Southern California and to the San Joaquin Valley in particular. Other fungus infections of the lung can be diagnosed from sputum cultures and the usual bilateral nature of the disease.

Neoplasm of the bronchus may give difficulty if associated with tubercle bacilli in the sputum. I have seen 2 such cases, both of which occurred in men of fifty and over. Age and sex therefore help in differentiating the two conditions. Bronchoscopy usually makes the proper diagnosis possible.

To reiterate, the commonest error is to confuse the pure type with pneumonia and to treat it as such for many weeks. This can largely be avoided if an inquiry concerning a history of tuberculous contact is made and appropriate sputum studies, together with serial x-ray examinations, are carried out in all young people acutely ill with pneumonitis.

The impure type rarely gives any trouble, because the associated evidence of ipsilateral or contralateral apical nodular or fibrotic involvement is practically pathognomonic of tuberculosis. The chest roentgenogram indicates the diagnosis, and studies of the sputum invariably confirm it.

PROGNOSIS AND TREATMENT

The prognosis of lower-lobe tuberculosis does not differ from that of disease elsewhere in the lung, depending in large part on the type of disease present. Productive or proliferative disease has a slow and benign course, whereas caseous pneumonic disease has a high morbidity and mortality if not actively treated. All the cases in the present series were either those of acute caseous pneumonia or of its sequela, the fibrocavernous type.

It is interesting to note that many of the earlier writers give an extremely poor prognosis to all basal lesions. In fact, Dunham and Norton²⁰ were so impressed by the typical course of these lesions that they called all progressive caseous pneumonic disease, whether or not found in the lower lobe, the basal type. They had a large percentage of Negroes in their series. Today, it is thought that the prog-

nosis largely depends on the type of lesion and not on its location.

The principles of treatment for lower-lobe tuberculosis do not differ from those for other lesions and in consequence open cavities must be closed as quickly as feasible. This means that in the acute pneumonic variety, before artificial pneumothorax can be initiated, bed rest is advised until caseation, sloughing and evacuation of the cavity contents have been accomplished and the surrounding pneumonitis has subsided. Not only are complications avoided by this regimen, but also on occasion one may be rewarded by a closed cavity and conversion of sputum, thus saving the patient years of prolonged collapse therapy. Except for one case, the entire series required a dynamic approach for ultimate control.

In the past, lower-lobe lesions have been a strong indication for interruption of the phrenic nerve, but it has been my experience, as well as that of many other workers, that there is little benefit to be derived from the procedure per se, especially where it is the sole means of providing rest and collapse. In fact, in the presence of acute disease it may constitute a distinct danger, since it may cause atelectasis of the lower lobe. Again, with diaphragmatic paralysis thoracoplasty may be dangerous until the function of the diaphragm returns, since atelectasis has been seen in the presence of an elevated diaphragm following such surgery. It seems certain that the only place for phrenic-nerve paralysis is as an adjunct to an existing pneumothorax or thoracoplasty.

In this series of cases, artificial pneumothorax was somewhat more successful in the pure group than in the impure, owing in large part to the paucity or even absence of adhesions in the former, which allows for more adequate collapse of the underlying lung without the necessity of supplementary procedures. This fact may be presented as presumptive evidence that the onset of the impure type is insidious and the disease of long standing. It is in these cases that one encounters the largest number of adhesions, not only about the base but around the apex.

Extrapleural pneumothorax has no place in this form of disease. Intrapleural pneumolysis should be used as a supplementary procedure to sever adhesions that are preventing the satisfactory collapse of the lung. Thoracoplasty has its place but should not be attempted until after long trial of bed rest and minor collapse procedures. When performed, it generally requires the resection of eleven ribs and often anterior section before closure of the cavity is obtained. More recently the tendency has been to make a bronchoscopic examination of all cases for bronchial lesions, since collapse therapy is of little value in those with ulceration. Lobectomy and pneumonectomy are procedures choice of in

certain of these cases, with complete extirpation of the disease as a possibility.²¹

SUMMARY

An analysis of tuberculous lesions in the lower lobe of the lung is made.

These lesions have been divided into two groups according to roentgenologic differences based on the presence or absence of associated apical involvement.

These two groups, named the "pure" and "impure" types, show distinct differences in sex, age, history of tuberculosis contact, the mode of onset and the side affected.

Theories of localization in the lower lobe are reviewed, and evidence for confirmation of Reisner's hypothesis is presented.

A method of treatment is outlined.

MEDICAL PROGRESS

THE PARATHYROID GLANDS AND PARATHORMONE*

ALFRED POPE, M.D.,† AND JOSEPH C. AUB, M.D.‡

IN RECENT years a number of excellent reviews on mineral metabolism and its control by the endocrine glands have appeared. Calcium and phosphorus metabolism was comprehensively reviewed by Schmidt and Greenberg¹ in 1935, and the more recent literature in this field was analyzed by Greenberg² in 1939 and by Cohn, Cohn and Aub³ in 1942. Recent advances in the knowledge of the chemistry of calcification were reviewed by Logan⁴ in 1940, the physiology of bone and of certain bone diseases by McLean⁵ in 1943, and various aspects of phosphorus metabolism by Guest and Rapoport⁶ in 1941 and by McLean⁷ in 1942. The literature on the relation of the endocrine glands to calcium metabolism was covered by Campbell and Turner⁸ in 1942, and special aspects of this problem have also recently been reviewed, such as the physiology and treatment of parathyroid diseases (Albright⁹), secondary hyperparathyroidism (Anderson¹⁰), calcium metabolism during pregnancy (Bodansky and Duff¹¹), the use of sterols in the treatment of hypo-

parathyroidism (McLean¹²) and the influence of the endocrine glands, including the parathyroid glands, on growth and aging by Silberberg and Silberberg.¹³ The extensive article by Campbell and Turner⁸ is not only a complete review of the literature concerning experimental studies on the parathyroid glands but also includes the report of many original observations on numerous aspects of this subject.

EXPERIMENTAL STUDIES

Mode of Action of Parathyroid Hormone

Considerable experimental evidence has been obtained in support both of the original theory of Collip that the chief action of the parathyroid hormone is directly on the solution of calcium salts from bone and of that of Albright, who has postulated that its action consists in promoting the re-excretion of phosphate.

Supportive evidence for the renal action of parathormone was obtained by Goadby and Stace who failed to obtain the normal phosphate diuresis in patients with chronic nephritis following injection of parathyroid extract, and by Goadby,¹⁵ who was able to correlate the degree of such phosphate diuresis inversely with the degree of severity of

*From the medical laboratories of the Collis P. Huntington Memorial Hospital, Harvard University, at the Massachusetts General Hospital. This is publication No. 587 of the Cancer Commission of Harvard University.

renal disease. Tweedy and his associates showed that no rise of the serum calcium level occurs after parathormone injection in bilaterally nephrectomized dogs¹⁶ or rats,¹⁷ that the response is normal in a unilaterally nephrectomized dog,¹⁸ and that nephrectomy protects dogs from the characteristic pathologic changes that develop after overdosage with parathyroid hormone in normal animals.^{16, 18} Harrison and Harrison¹⁹ have developed a method for the quantitative determination of the amount of phosphate resorbed from the renal tubules, and have shown that in dogs following parathormone administration there is a decrease in the rate of maximal resorption, with reduction in the level of serum inorganic phosphorus. Induced acidosis resulted in the same reduction in tubular resorption of phosphate as parathormone.²⁰ Fay, Behrmann and Buck,²¹ on the other hand, found no difference in the renal clearance of phosphate and creatinine between normal, hyperparathyroid and parathyroidectomized dogs. Brull and Carbonesco²² concluded from the results of a cross-circulation experiment that parathyroidectomy reduces the excretion of renal phosphate owing to a purely renal effect. Neufeld and Collip²³ produced renal insufficiency in dogs, rats and cats in a variety of ways and were unable to demonstrate any change in the serum calcium level following the administration of parathyroid extract. These authors also found that in normal animals continuous administration of disodium phosphate with parathormone resulted in the maintenance of normal values of serum calcium and phosphorus. All these findings favor the theory of increased renal excretion of phosphate under the influence of parathyroid hormone.

On the other hand, Ellsworth and Fitcher²⁴ found a rise in the serum calcium level after treatment of nephrectomized dogs with parathyroid extract, and concluded that the renal elimination of phosphorus was not prerequisite to this rise. After similar treatment of chronic nephritic patients a rise in the calcium levels sometimes occurred after twenty-four hours,²⁴ and in nephrectomized rats similarly treated, although no rise of this level was observed, osteoclastic resorption of bone was demonstrated.¹⁷ Similarly, Seyle²⁵ found that in rats nephrectomy does not prevent the characteristic osteoclastic resorption of bone that follows administration of parathormone, whereas parathyroidectomy does prevent the much less striking bone changes that result from nephrectomy alone. Logan²⁶ obtained the typical rise of urinary and fall of serum phosphorus levels after injection of parathyroid extract into normal dogs, but also observed a rise in the serum calcium level within one hour whether or not the phosphorus level was simultaneously lowered. Moreover, twelve to twenty-four hours later both the calcium and phosphorus levels of the serum were elevated. Ingalls, Donald-

son and Albright²⁷ studied the effects of parathormone on nephrectomized rats and found definite decalcification of bone, due specifically to the hormone. McLean and Bloom²⁸ demonstrated bone salt in the trabeculae of spongy bone of rats and puppies under the influence of parathyroid extract, both being transported to the marrow vessels and within marrow macrophages. Moore,²⁹ however, did similar experiments in rats and found that deposition of calcium phosphate in the bone marrow was always associated with focal tissue degeneration and similar deposits in other tissues. The effect of an extremely active parathormone preparation on the rate of hydrolysis of glycerophosphate by kidney phosphatase was studied by Wood and Ross³⁰ who found that the accelerating action of the hormone was nonspecific and no greater than that of serum or egg albumin. Although these studies in no way discredit the theory of increased excretion of renal phosphate under the influence of the parathyroid hormone, they do suggest that the latter may have a direct demineralizing action on the bones as well.

Cantarow and his associates,^{31, 32} from a study of the partition of calcium and phosphorus between serum and physiologic saline solution injected into the peritoneal cavity of dogs, have concluded that the fundamental action of the parathyroid hormone is to promote the diffusion of calcium from the blood into the various tissue fluids, the source being the solution of bone salts.

Miscellaneous studies on the action of parathormone include the demonstration of a rise in phosphatase activity of serum³³ and of the long bones.^{34, 35} Roche and Filippi³⁵ believe this to be due to an increase in the concentration of enzyme activators at these sites. Cantarow, Haury and Whitbeck³⁶ found that in dogs parathormone caused a drop in the serum magnesium level, with a rise in that of the peritoneal fluid. Previously, Tibbetts and Aub³⁷ had shown that magnesium excretion is normal in hyperparathyroidism, although cure of the disease is accompanied by a temporary fall and parathormone administration by a temporary rise of this element in the urine. Increase in the magnesium intake resulted in an increase in the calcium excretion, and these authors suggest that magnesium may be substituted for calcium in the bones in this disease. Cantarow, Brundage and Housel³⁸ report hyperproteinemia due to hemoconcentration in experimental hyperparathyroidism in dogs. Shelling, Kajdi and Guth³⁸ found that after the injection of parathyroid extract into dogs there was a marked initial diuresis, with a resultant loss of water and electrolytes, which, if repeated, was followed by the usual syndrome of parathyroid "poisoning," with urinary suppression and death. They were able to prevent the latter condition by replacement of fluid and electrolytes, and concluded from this that de-

hydration is an important element in this experimental syndrome. Intestinal absorption of calcium is not affected by oversecretion of parathyroid hormone.³⁹ Cantarow, Stewart and Housel⁴⁰ have studied the pathologic effects of large doses of parathormone in dogs and report both calcification and extensive degenerative changes in the viscera. Bedinger, Kendrick and Keeton⁴¹ studied the toxic effects of calcium administered intravenously to dogs, and among other observations recorded that parathyroidectomy with a low initial serum calcium level affords no protection against these. Logan, Christensen and Kirklin⁴² were able to detect only a very slight rise in the urinary calcium level following injection of thyroid into thyro-parathyroidectomized dogs, and believed that this might indicate that the parathyroid glands are necessary for the rise of this level that usually follows such administration, although they also pointed out that the low initial level of serum calcium in these animals might in itself have prevented this characteristic effect of thyroid. Schiffrin⁴³ has reported the effects of parathormone on the gastric secretion of dogs; these are mainly a reduction of the volume and acidity and an increase of the enzyme concentration. The reverse effects result from thyro-parathyroidectomy and are due specifically to the lack of parathyroid hormone.

Relation between Parathyroid Hormone, Vitamin D and Dihydratichysterol

The relation between the parathyroid hormone, vitamin D and A. T. 10 (dihydratichysterol) has been extensively studied by Albright and his associates,⁴⁴⁻⁴⁶ who as a result of their comparison of the action of these agents in hypoparathyroidism and rickets have developed the theory that both vitamin D and A. T. 10 increase the absorption of calcium and that all three substances promote the excretion of phosphorus in the urine, but that vitamin D acts chiefly on calcium absorption, whereas parathyroid hormone acts exclusively on phosphorus excretion. A. T. 10 acts only feebly in its enhancement of calcium absorption but is extremely active in promoting the excretion of urinary phosphorus. Hence it is not antirachitic but is a good therapeutic agent for hypoparathyroidism.

Experimental evidence in support of this thesis has appeared. Thus, Shohl, Fan and Farber⁴⁷ reported that nontoxic doses of A. T. 10 prevented rickets in rats due to a low calcium and high phosphorus level but not that due to a high-calcium and low-phosphorus diet. They made the reasonable assumption that it was effective in the former by causing a greater excretion of phosphorus in the urine, thus rendering the diet less rachitogenic. Shohl and Farber⁴⁸ then showed that in approximately toxic amounts A. T. 10 nullifies the rachitogenic effects of a high-calcium and low-phosphorus diet, which is evidence that it does promote cal-

cium absorption in large doses and is therefore weakly antirachitic, although only one four-hundredth as active in this respect as vitamin D. Bastenie and Zylberszac⁴⁹ found that small doses of A. T. 10 resulted in inhibition of mitoses in the parathyroid glands of rats. They assumed that this effect was secondary to the high level of serum calcium induced by this drug. A similar inhibition of mitoses in the parathyroid glands of rats treated with large doses of A. T. 10 was observed by Campbell and Turner.⁸

Rose and Sunderman⁵⁰ studied 5 patients with postoperative parathyroid deficiency and found that A. T. 10 was extremely effective in controlling symptoms and maintaining a normal concentration of serum calcium. Himsworth and Maizels⁵¹ compared the efficacy of vitamin D and that of A. T. 10 in the control of a case of idiopathic hypoparathyroidism. Both were effective, but the former was somewhat more reliable and capable of giving perfect control of the serum calcium level if given in sufficiently large doses. Blum⁵² has reported excellent clinical results with the use of this agent for the control of hypoparathyroidism, and Rya and McCullagh⁵³ were similarly successful. All these authors found that A. T. 10 alleviated the symptoms of parathyroid insufficiency, promoted the excretion of calcium and phosphorus in the urine and controlled the serum concentrations of these substances. They consider that feeding large amounts of calcium by mouth increases the efficiency of the drug and thereby reduces the dosage of the latter necessary to control the disease.

McLean¹² has reviewed the clinical and experimental evidence on this subject and has concluded that vitamin D and A. T. 10 are equally effective in the control of parathyroid insufficiency, provided that the former is given in adequate amounts, the calcemic dosage being one hundred to two hundred times greater than the antirachitic. McLean¹² concluded that unsatisfactory results obtained with the use of vitamin D as a calcemic agent were due solely to inadequate dosage. A discussion of the relative merits of vitamin D and A. T. 10 in treating hypoparathyroidism was included in a presentation of such cases by Cutting, Wells and Carnes.⁵⁴ They found the two drugs about equally efficacious, but one of their patients was definitely refractory to A. T. 10. Sevringhaus and St. John⁵⁵ have recently reported on the continuation and confirmation of an earlier study⁵⁶ of patients with severe permanent hypoparathyroidism in whom the deficiency was perfectly controlled with vitamin D and calcium salts.

Factors Affecting the Activity of Parathyroid Gland

The pituitary and other endocrine glands. Some attention has been given to the possible elaboration of a parathyrotropic factor by the pituitary gland. Friedgood and McLean⁵⁷ found that guinea pig

injected with anterior-pituitary extract developed significant elevations of the serum calcium level. Although there was no change in the level of serum inorganic phosphorus, they interpreted these results as indicating the presence of a parathyrotropic factor in the anterior-pituitary preparation. A similar interpretation was placed by Ham and Haist⁵³ on their observation that anterior-pituitary extract produced a large number of mitoses in the parathyroid tissue of dogs. Blumenthal and Loeb⁵⁵ found that acid extracts of the anterior pituitary gland, hypophyseal implants and potassium iodide all increased the mitotic activity of the thyroid gland and parathyroid glands of guinea pigs, whereas underfeeding and thyroid produced the reverse effect. On the other hand, Carnes, Osobold and Stock⁶⁰ observed no evidence of impairment of parathyroid function in hypophysectomized rats. The serum calcium and phosphorus concentrations remained normal even under the stress of a low-calcium diet, and hypophysectomized and parathyroidectomized rats behaved in every way like those with parathyroidectomy alone. Similarly, Snyder and Twcedy⁶¹ were unable to detect any alteration in the serum calcium level and actually found a slight rise in the phosphorus level following treatment of rats with anterior-pituitary extract. In hypophysectomized monkeys Baker⁶² found a slight atrophy of the parathyroid glands as measured by size and cell count but no change in the histologic or cytologic characteristics of the cells. Campbell and Turner⁶ made extensive studies of the effect of anterior-pituitary extract on the weights and mitotic activities of the parathyroid glands of several species and concluded that the existence of a parathyrotropic factor is highly doubtful. In toads, Schrire⁶³ found no difference in the effect of injected parathyroid extract on the level of plasma inorganic phosphate between normal and hypophysectomized animals. Thus, evidence for a relation between the parathyroid glands and the anterior pituitary gland is neither consistent nor conclusive. If such a relation exists, it is probably not an extremely close one, for the former appear to be able to function even when the anterior pituitary is removed.

In rats, Bastenie and Zylberszac⁶⁴ found that folliculin inhibited and progesterone and castration stimulated the mitotic activity of the parathyroid glands. The folliculin effect was inhibited by progesterone, and the castration effect by folliculin. Treatment with both hormones greatly stimulated mitoses in the parathyroid glands of castrated but not in those of normal rats. Campbell and Turner,⁶ on the other hand, observed no change in the mitoses of the parathyroid glands of chicks treated with estradiol benzoate. Nathanson, Brues and Rawson⁶⁵ have shown that testosterone stimulates mitoses in the parathyroid glands of rats. Similar effects on the thyroid glands of these animals were ob-

served, and since testosterone in moderate doses is known to stimulate ovarian activity through the intermediation of the pituitary gland, these authors suggested that the observed effect on the parathyroid and thyroid was also via the hypophysis. Campbell and Turner⁶ were unable to confirm these findings. Bloom, McLean and Bloom⁶⁶ found that parathyroid extract abolished the proliferative endosteal reaction in medullary bone, which is a characteristic phenomenon preparative to new-bone formation following the combined administration of estrogens and androgens in pigeons.

Pregnancy. Bodansky and Duff¹¹ have stated that somewhat low serum calcium values are to be expected in pregnancy and are not to be regarded as abnormal if not below 8.5 mg. per 100 cc. Severe hypocalcemia means either parathyroid deficiency or nutritional inadequacy and results in skeletal abnormalities in the fetus. These authors regard a slightly high fetal serum calcium level as normal. In studies on rats, they found some demineralization of bones in the presence of normal serum calcium levels, presumably owing to stimulation of the parathyroid glands by a lowered serum calcium level. In parathyroidectomized animals, on the other hand, in which the skeleton showed no changes in density, lowered serum calcium levels did develop, and tetany occurred near term. It was found that pregnancy converted latent into active hypoparathyroidism in these animals, and that this condition could be cured by a high-calcium and low-phosphorus diet. Bodansky⁶⁷ studied the mineral metabolism of pregnant women and observed evidence of increase in the size and functional activity of the parathyroid glands such that he characterized pregnancy as a state accompanied by a minor degree of hyperparathyroidism. He found a rise of serum phosphatase activity in the last trimester, accompanied, however, by a slight degree of hypocalcemia and little change in serum inorganic phosphorus. In a similar vein, Sinclair⁶⁸ showed that pregnancy resulted in marked hypertrophy of the parathyroid glands of rats and that multiparity had a cumulative action in this respect. The hypertrophy could be prevented by a high-calcium and low-phosphorus diet but was enhanced by a diet low in calcium and rich in phosphorus. Similar effects of pregnancy on the volume of the parathyroid glands of rats were reported by Oppen and Thale.⁶⁹

In studying the relation of parathyroid activity to pregnancy in rats, Bodansky and Duff⁷⁰ found that parathyroidectomy resulted in diminished fertility and reduction in the number and birth weight of the fetuses. These effects were minimized by feeding a high-calcium and low-phosphorus diet. In addition, the parathyroidectomized animals underwent a prolongation of gestation, showed tetany at term and suffered a high rate of maternal

and fetal mortality. These effects were abolished by a high-calcium and low-phosphorus diet. In another study,⁷¹ pregnant parathyroidectomized rats were again shown to be unable to mobilize calcium from their bones, so that the latter retained their normal pregestational weight and hypocalcemia developed. With a rachitogenic diet with a high calcium-to-phosphorus ratio, the differences in bone weights between the pregnant parathyroidectomized and normal control rats were abolished.

Cantarow, Stewart and Housel⁴⁰ noted that in the case of a pregnant dog treated with toxic amounts of parathyroid extract and from which nine normal living fetuses were obtained, none of the characteristic pathologic changes observed in the mother were found in the fetuses, suggesting that the parathyroid hormone cannot pass the placental barrier. Bodansky and Duff,⁷² from studies on fetal growth and storage of calcium and phosphorus with varying conditions of diet and parathyroid function in pregnant rats, concluded that fetal growth and mineral storage depend entirely on suitable concentrations of calcium and phosphorus in the maternal blood, which it was assumed are accurately reflected in the fetal blood as well. Sinclair⁷³ found that the parathyroid glands of fetal rats were twice as large in proportion to the body weight as those of adults and were affected by the diet of the mother as a result of changes in her serum calcium or phosphorus level. A diet with a normal ratio of calcium to phosphorus caused enlargement of maternal parathyroid glands, and one with more calcium and less phosphorus tended to suppress changes in both maternal and fetal glands. Such a diet, however, was effective therapeutically after maternal parathyroidectomy. A normal diet to which aluminum acetate was added to reduce phosphate absorption was equally effective under these circumstances. The parathyroid glands of fetal rats were depressed by a high serum calcium or inorganic phosphorus level in the mother. Sinclair found the total weight of the tissue of all the parathyroid glands in fetal animals to be only 5 per cent of that of adults, so that it is probable that pregnancy can afford little protection against the consequences of parathyroidectomy in the mother. It appears clear from these as well as previous studies that pregnancy exerts a great strain on the parathyroid calcium system of the mother, and that this is a period of human life when most careful attention should be given to the calcium and phosphorus content of the diet.

Diet and serum calcium level. Baumann and Sprinson⁷⁴ have produced experimental hyperparathyroidism in rabbits by feeding a high-phosphorus and low-calcium diet. The parathyroid glands enlarged with hypertrophy of the cells, and an increase in the amount of circulating parathyroid hormone was suggested by results obtained with

the technic of Hamilton and Schwartz. Ham, Littner, Drake, Robertson and Tisdall⁷⁵ concluded from their experiments that parathyroid hypertrophy occurs only in low-calcium, not in low-phosphorus, rickets and that it is a function only of the serum calcium level. They interpreted their results as indicating that hypocalcemia, not hyperphosphatemia, is the factor that stimulates parathyroid activity. DeRobertis,⁷⁶ on the other hand, has reported that parathyroid hypertrophy, with enlargement and hyperplasia of the cells whose cytologic characteristics become suggestive of marked functional activity, occurs both in rats with low-calcium and in those with low-phosphorus rickets, although the effect is more striking in the former. Similar studies on rats by Carnes, Pappenheimer and Stoerk⁷⁷ also revealed that an increase in parathyroid volume occurs on a low-calcium and a decrease on a low-phosphorus diet. When the calcium of the diet was maintained at a constant value, the parathyroid volume was approximately proportional to the amount of dietary phosphorus. The giving of viosterol led to a rise of both serum calcium and phosphorus with a low-phosphorus diet and enhanced the diminution in size of the parathyroid glands. This agent, however, caused an inhibition of the parathyroid enlargement obtained with a low-calcium diet.

Patt and his associates^{78, 79} studied the effects of oxalate and of perfusion of the parathyroid glands with decalcified and normal blood on the serum calcium of normal and parathyroidectomized dogs. They concluded that a lowering of the serum calcium level directly stimulates the glands to produce more hormone. Selye²⁵ noted that parathyroid extract exhibited its usual action in rats previously subjected to partial thyroidectomy or partial hepatectomy, and concluded that the activity of this hormone is not affected by either the liver or the thyroid gland.

An interesting corollary to the effect of diet on the functional activity of the parathyroid glands is the effect of the latter on the mineral appetite of experimental animals. The work of Richter and his associates has shown that the appetite of rats for calcium lactate⁸⁰ and other calcium salt solutions⁸¹ is markedly increased by parathyroidectomy, this change being reversed by parathyroid implants,⁸⁰ the injection of large amounts of parathyroid hormone or the addition to the diet of various materials rich in vitamin D or of A.T. 10.⁸² An increase in the appetite for strontium and magnesium salts and an aversion to disodium phosphate solution were also observed following parathyroidectomy.⁸¹ Richter and Birmingham⁸² have utilized this appetite method for the bioassay of various substances having an effect on the metabolism of calcium. Wilens and Waller,⁸³ using the method of Richter,⁸⁰ showed that partially nephrectomized rats voluntarily consume increased

counts of water and the same amount of calcium preoperatively but decreased amounts of phosphorus. Parathyroidectomized rats increase their calcium and decrease their phosphorus intake, and such animals subjected to partial nephrectomy will consume an even greater amount of calcium and small amounts of phosphorus.

The kidneys and renal function. The fact that reactivity of the parathyroid glands can produce renal damage has always been of interest, and here is a nephritis produced by one's own secretions. Renal insufficiency may also produce an enlargement of the parathyroid glands, and additional work on this subject has recently been reported. The investigations of Donohue, Spingarn and Pappenheimer⁸⁴ showed that partially nephrectomized rats exhibited an increase in the calcium of the remaining renal substance. This was apparently associated with an observed coincident parathyroid enlargement, for it could be prevented by parathyroidectomy. Duguid⁸⁵ found that in rats with chronic nephritis due to a high-phosphate, high-vitamin D diet, parathyroid hypertrophy occurred, but since it was found also in animals on such a diet that did not develop renal changes, he concluded that it was the result of a disturbance of phosphorus metabolism and that the relation to nephritis was still uncertain. Chown and his co-workers^{86, 87} have studied the renal pathologic changes that develop after administration of parathyroid extract to rats, and believe that they result from calcium deposition both inside and outside of the nephrons, causing obstruction with either atrophic changes or tubular dilatation. The gross lesions observed fell into three categories: cystic dilatation of the tubules, irregular dilatation of the pelvis and chronic focal nephritis. The authors suggest that disturbances in mineral metabolism may be the background for some clinical cases of polycystic kidneys and pyelonephritis.

The Parathyroid Glands and Growth, Repair of Fractures and So Forth

In an extensive study of the effects of parathyroid extracts on the skeletons of growing rats, Burrows⁸⁸ found that the hormone caused a retardation of growth and hypoplasia of the parathyroid tissue. On the skeleton the early effects consisted of the classic type of demineralization and the production of characteristic osteitis fibrosa. If administration of the extract was continued, a reversal of this phenomenon was observed, and marked osteoblastic activity brought about a state akin to marble bone disease. Later this effect also tended to diminish, and the bones to return to an essentially normal state. The author has discussed the possible significance of these findings.

Roche and Mourgue⁸⁹ have reported that in pigeons with experimental fractures treated with vitamin D₂ or parathyroid hormone, although there

was no acceleration of callus formation, there was a significant increase in the bone salt content of the calluses of the treated pigeons over that of the calluses of the untreated controls. In the parathyroid-treated birds mild generalized skeletal demineralization occurred. These authors discuss the therapeutic implications of these findings in the treatment of fractures. Silberberg and Silberberg⁹⁰ have recently shown that in mice parathyroid hormone causes hypertrophy, calcification and breakdown of growing epiphyseal cartilage plates. The hormone results in osteoblastic but not in cartilaginous proliferation. Since there was acceleration of epiphyseal closure, the authors concluded that the hormone speeds up the characteristic changes observed in the normal aging process of the skeleton. In old mice with united epiphyses, calcification of inactive cartilage and increased bone formation occurred after parathormone treatment. Similar effects were obtained with the use of calcium gluconate, but combination of the latter with parathormone, although producing a marked increase in bone formation, had no effect on the changes typical of skeletal aging. These observations are interesting, but it must be borne in mind that the reactions of the bones in rats and birds are not the same as those observed in dogs and men.

The Nature of Parathyroid Hormone

Ross and Wood⁹¹ have developed a method for preparing a parathyroid extract that apparently consists of relatively pure parathyroid hormone and that has triple the potency of all previous extracts. Ultracentrifugation showed the presence of two gross molecular species, the molecular weight of one being in the neighborhood of 20,000 and that of the other between 500,000 and 1,000,000. After complete sedimentation of the latter, 50 per cent of the hormonal activity was retained in the mother liquor, suggesting that the smaller molecule is the parathyroid hormone. Pepsin digestion of the whole extract destroyed its activity, ultraviolet absorption studies revealed no chromophoric prosthetic group, and the preparation was stable to electrodialysis, showing that the hormone has no loosely bound polar groups of low molecular weight. These studies therefore confirm the previously suspected protein nature of the parathyroid hormone, which is further strengthened by the studies of Wood and Ross⁹² on the ketene acetylation of the hormone, the result of which is complete inactivation, not reversed by subsequent hydrolysis. From this the authors conclude that free amino groups are necessary for the physiologic activity of the hormone.

CLINICAL ASPECTS

Hypoparathyroidism

Drake, Albright, Baer and Castleman⁹³ have discussed the criteria necessary for making the

diagnosis of chronic idiopathic hypoparathyroidism and consider that the following clinical findings are necessary prerequisites: a low serum calcium level, a high serum inorganic phosphorus level, a normal skeleton by roentgenography and absence of all signs of renal insufficiency. These authors review all the available proved cases of the disease and discuss possible etiologic factors. The pathologic findings in 1 of the 2 proved cases in which these are available are cited, and include complete replacement of all the epithelial cells of the parathyroid glands by fat. In the case with post-mortem findings reported by Cantarow, Stewart and Morgan,⁹⁴ no parathyroid tissue was identified.

McQuarrie, Hansen and Zeigler⁹⁵ studied factors affecting tetany production in a case of idiopathic hypoparathyroidism apart from the level of serum calcium. They found that a low-mineral diet increased the convulsive tendency as provoked by various kinds of stimuli, whereas a high-mineral diet had the opposite effect even without changes in the levels of serum calcium and phosphorus. Hyperventilation induced tetany during feeding of a low-mineral but not of a high-mineral diet. Tetany produced by the antidiuretic effect of posterior-pituitary extract was lessened by addition of salt, which presumably cut down the dilution of the extracellular fluid due to water retention. The authors concluded that in hypoparathyroidism the convulsive tendency is due to more than a low serum calcium level. This is in line with the findings of Evans, Szurek and Kern⁹⁶ in surviving parathyroidectomized dogs. These investigators found that such animals remained in latent survival with low serum calcium and high serum phosphorus levels without showing signs of tetany, and concluded that some adjustment in neuromuscular irritability must occur so that it becomes normal in spite of an abnormal electrolyte pattern in the tissue fluids.

Robertson⁹⁷ has reported studies on calcium and phosphorus metabolism in cases of postoperative tetany. He found the usual fall in the urinary phosphorus level and elevation of the serum phosphorus level with a drop in both serum and urinary calcium levels, but noted that a fall of the urinary phosphorus level might also occur in uncomplicated thyroidectomy. He also observed in a patient with a serum calcium level of 5.5 mg. per 100 cc. that a normal ratio of fecal to urinary calcium excretion was maintained. This appeared to him to render unlikely the theory that a serum calcium level of about 8.5 mg. per 100 cc. is the renal threshold level for its excretion.

Albright, Burnett, Parson and Sulkowitch⁹⁸ state that in the case of a patient with hypoparathyroidism whom they studied the ingestion of aluminum hydroxide caused a lowering of the serum phosphorus level and an elevation of the serum calcium level, the effect presumably being due to de-

creased phosphorus absorption as a result of the formation of insoluble aluminum phosphate compounds in the bowel.

Several examples of the not uncommon trophic disturbances in tissue of ectodermal origin, including skin lesions, loss of nails and hair and cataract formation, in association with hypoparathyroidism have been reported.^{99, 100} Albright, Burnett, Smith and Parson¹⁰¹ have called attention to a syndrome that they term "pseudohypoparathyroidism" in which the classic clinical and laboratory manifestations of parathyroid insufficiency are present, but in which the essential disturbance is apparently not a lack of parathyroid hormone but rather a failure of end-organs to respond normally to it, since the changes are not reversed by its administration and phosphate diuresis similarly fails to occur. In 1 of 3 such patients studied, normal parathyroid tissue was observed at biopsy. Recently Sutphen, Albright and McCune¹⁰² have reported on the remarkable occurrence of hypoparathyroidism in 3 siblings; in 2 of these cases the disease was associated with widespread moniliasis, and presumably also in the third. Two other cases of association of these diseases were cited, together with 2 cases of associated moniliasis and Addison's disease, in 1 of which there was also hypoparathyroidism. The times of onset of symptoms in these cases suggested that the moniliasis preceded the parathyroid insufficiency. The authors have discussed the possible etiologic significance and relations of these unusual observations.

Hyperparathyroidism

An enlightening résumé of the historical development of knowledge concerning this disease may be found in a recent article by Cope,¹⁰³ which also includes an excellent discussion of the two types of pathologic changes that may result in clinical hyperparathyroidism, either adenoma or hyperplasia of the glands. Soffer and Cohn¹⁰⁴ have prepared a review of the literature on primary and secondary hyperparathyroidism, together with a presentation of 5 primary and 4 secondary examples of this disease. One of their cases is of special interest in that the patient apparently had a primary adenoma with hyperparathyroidism that resulted in renal damage and chronic renal disease, the latter, in turn, leading to secondary hyperplasia of the other parathyroid glands. A similar case was studied by Downs and Scott,¹⁰⁵ who were able to reconstruct such a clinical course on the basis of autopsy findings. Snapper¹⁰⁶ has presented an analysis of 3 cases of parathyroid adenoma, 1 of which was of interest because of the finding of a low urinary calcium in combination with the usual biochemical changes associated with hyperparathyroidism. This was attributed to a probable superimposed vitamin D deficiency. Lage and Greene¹⁰⁷ have reported 13 cases of hyper-

parathyroidism from the Middle Western states, an area in which this disease is considered a great rarity. Anspach and Clifton¹⁰⁸ studied 2 cases of parathyroid adenoma in children. In 1 case the onset of the disorder was at three months of age, the youngest such patient known. Another unique feature reported was relief of symptoms and good recalcification of the skeleton following x-radiation of the neck. Jacox, King and Bailey^{109, 110} studied a patient with clinical hyperparathyroidism and advanced bone lesions in whom no parathyroid tumor or hyperplasia could be demonstrated surgically and in whom some recalcification of the skeleton, improvement in blood chemical findings and symptomatic relief followed x-radiation of the neck. The patient subsequently died of renal failure, apparently secondary to calculus formation and obstruction of the urinary tract. At autopsy no parathyroid tissue was identified, presumably because of the radiation therapy. It is difficult to account for the fact that the patient terminally still exhibited the blood findings characteristic of hyperparathyroidism. Cope^{111, 112} has discussed the surgical management of hyperparathyroidism and laid stress on the specialized knowledge, training and technics involved. An analysis of the distribution of parathyroid tissue, together with observations concerning recognition of its normal and abnormal states and details concerning the surgical removal of diseased glands, are included, as well as a description of the two-stage exploratory procedure used in such cases at the Massachusetts General Hospital. In these operations an initial exploration of the neck and posterior mediastinum is made, and if no parathyroid adenoma or hyperplasia is discovered, search for a tumor in the anterior mediastinum is made at a second session. Three cases of parathyroid adenoma, 2 with unusually located tumors, were reported by Cochran,¹¹³ whose results led him to suggest the possible efficacy of partial as against complete removal of such lesions. Meyer and Ragins¹¹⁴ have reported the clinical and pathological findings in a remarkable case of proved parathyroid carcinoma with hyperparathyroidism, fibrocystic disease and renal lithiasis, all three of which conditions improved after excision of the original tumor but reappeared with recurrence of the lesion and the development of metastases. This is an extremely rare condition.

Hansman and Carr Fraser¹¹⁵ found that in patients with hyperthyroidism generally, but not invariably, there was an associated negative calcium-and-phosphorus balance that could not be correlated with the change in metabolic rate and was unaffected by Lugol's solution. The balance was, however, rendered normal by radiation therapy. These findings led them to conclude that hyperfunction of the thyroid gland and that of the parathyroid glands are often associated, and that the plastic parathyroid cells are radiosensitive.

view of such cases has been presented in connection with the report of a case by Miller and Evans¹¹⁶ of simultaneous thyroid hyperplasia and parathyroid adenoma proved pathologically. A topic of interest in connection with hyperparathyroidism is the finding by Klenshoj and Koepf¹¹⁷ of a high acid as well as a high alkaline phosphatase level in the serum of a patient proved to have this disease. This is the only reported example of another disease in which the acid phosphatase level was elevated to the same extent as occurs in carcinoma of the prostate with skeletal metastases. The fact that the presenting symptoms of hyperparathyroidism may be the result of changes in the oral cavity has been brought out by Strock¹¹⁸ in a discussion of the dental symptoms that may be associated with this disorder.

The subject of secondary hyperparathyroidism has been well reviewed by Anderson.¹² Herbert, Miller and Richardson¹¹⁹ have studied a case of chronic renal disease with secondary parathyroid hyperplasia, decalcification of bone and metastatic calcification and have reviewed similar cases. They have attempted to set a standard for the saturation level of serum calcium and phosphorus above which metastatic calcification may be expected to occur. This they anticipate only in cases such as the one presented in which the combination of renal disease and secondary hyperparathyroidism produced an elevated serum phosphorus level together with a normal or high serum calcium level. Ginzler and Jaffe,¹²⁰ however, have concluded that the osseous lesions of chronic renal disease are usually the result of acidosis rather than of hyperfunction of the parathyroid glands, which in most cases were only mildly hyperplastic. The problem of secondary hyperparathyroidism produced by obstructive lesions of the urinary tract in children has been discussed by Harrison,¹²¹ who reports clinical observations and the results of treatment of 5 such patients.

Albright, Burnett, Cope and Parson¹²² have published an excellent short discussion of their views concerning the active metabolism of bone and the fundamental physiologic disturbances underlying the development of osteitis fibrosa, osteoporosis and osteomalacia. They point out that although the serum calcium, phosphorus and phosphatase values are normal in osteoporosis, since there is hypercalciuria, renal damage may ensue, and hypercalcemia may develop, especially if the rate of calcium excretion is insufficient to keep up with that of demineralization of the bones. Under these circumstances a mistaken diagnosis of hyperparathyroidism is likely to be made, and these authors have presented a case illustrating this possibility.

From the foregoing discussion it should be clear that in the last few years considerable progress has been made in the understanding of both the normal and the pathologic physiology of the parathyroid glands.

glands. Experimental studies have indicated that the parathyroid hormone probably acts both to promote the renal excretion of inorganic phosphorus and to bring about directly the solution of bone salts. Clinical and physiologic investigations have greatly clarified the modes of action and relations of parathyroid hormone, vitamin D and A.T.10. The treatment of hypoparathyroidism has been rendered simple and effective, and the surgical management of hyperparathyroidism placed on a sound basis.

CASE 30231

PRESENTATION OF CASE

First admission. A thirty-four-year-old woman was admitted to the hospital because of jaundice and fatigue.

About one year before admission, the patient was sent to the Out Patient Department because of two positive Hinton tests. There was no history of primary or secondary syphilis. Repeat Wassermann and Hinton tests were positive. X-ray studies of the chest and cerebrospinal fluid examinations were negative. Physical examination was also entirely negative. Treatment with bismuth and subcarbonate was started, and she received twelve doses of 0.2 gm. each, followed by eight injections of Mapharsen of 0.03-0.04 gm. each. After each injection of Mapharsen she had nausea and vomiting for one or two days and felt weak. She was given another course of bismuth subcarbonate (0.2 gm.) and seven intravenous injections of neoarsphenamine (0.45 gm.). Her general weakness, tiredness, headache, various joint aches and occasional nausea and vomiting continued and became constant, and she was forced to give up her job. She had no appetite and lost about 28 pounds in weight. In the last few weeks of the treatment she began to notice a steadily increasing yellowish pigmentation of the skin. All her symptoms seemed to become aggravated and she was admitted to the hospital.

Examination showed a thin, alert woman. The skin was dry and "jaundiced," the color being described as yellowish brown on the face, dorsum of hands and knees and brown on the palmar creases. There was a "bismuth line" around the teeth. Small patches of ecchymoses and hemorrhagic spots were seen on the back and on the inner surfaces of the lower extremities. There was yellowish pigmentation of the scleras and conjunctivas. Generalized enlargement of the cervical, axillary and epitrochlear lymph nodes was noted, but examination was otherwise essentially normal.

The blood pressure was 100 systolic, 70 diastolic. The temperature was 98°F., the pulse 90, and the respirations 20.

*On leave of absence.

Examination of the blood showed a red-cell count of 4,650,000, with a hemoglobin of 14.2 gm. The white-cell count was 9900, with 66 per cent neutrophils. The urine was acid and had a specific gravity of 1.030. A foam test was positive for bile; there was a + test for acetone and a rare hyaline cast. The stools were light yellow to brown and occasionally guaiac positive. The blood protein was 5.9 gm. per 100 cc. The prothrombin time was 20 seconds (normal, 20 seconds), and the hematocrit 51. The van den Bergh was 6.4 mg. per 100 cc. direct, and 9.3 mg. indirect. The blood chloride was 83.6 milliequiv. per liter. Repeat chloride determinations were 96.7 and 91.4 milliequiv. per liter. The sodium was 128.2 milliequiv. per liter; the blood sugar was 82 mg. per 100 cc. The carbon dioxide combining power was 21.8 millimols per liter. A glucose tolerance test revealed a fasting blood sugar of 36 mg. per 100 cc., 162 mg. at the end of one hour, 85 mg. at the end of two hours, and 64, 59 and 43 mg. at subsequent successive half-hour periods. A cephalin flocculation test was + in twenty-four and forty-eight hours.

The patient continued to vomit and was given daily infusions of glucose and saline solutions and several transfusions. The electrolyte levels were sustained by this method, but she continued to take and retain little by mouth. The vomitus varied in amount, was guaiac negative and contained free hydrochloric acid. A mousy odor was noted in the breath. A blue-gray streaking of the hard palate and the undersurface of the tongue and patches on the buccal mucosa were seen at the end of the first week. A plain film of the abdomen showed no areas of calcification. A 17-ketosteroid determination showed that 2.8 mg. was excreted in twenty-four hours. After the first week she received daily doses of sodium acid phosphate, Hykinone and sodium chloride. The vomiting stopped, and she was able to take and retain a high-calorie, high-vitamin diet. Although still jaundiced, the van den Bergh dropped to 1.2 mg. direct and 1.8 mg. indirect and the cephalin flocculation time became zero; the blood sodium remained at about 128 milliequiv. per liter. The patient was finally discharged two months after admission.

Second admission (three months later). Following discharge the patient did well, had no nausea or vomiting and gained about 3 pounds. She had considerable craving for salt, but whether this was real or merely because she had been advised to use more salt could not be ascertained. The pigmentation disappeared from the scleras but was persistent in the skin. For the first time in her life, however, she was bothered by the cold and her hands and feet blanched on exposure to cold. About two months after discharge she had a mild upper respiratory infection, felt extremely tired and depressed and had no appetite. She recovered from this episode, however, and for the next three weeks

felt fairly well. About a week before readmission, she contracted another cold. In the next few days she became gradually weaker and more tired. Two days before admission she commenced to vomit after eating or drinking. This progressed and became almost constant. One hour before entry she developed a dull, steady, slight pain in the epigastrium, which extended under the sternum.

Physical examination showed an emaciated woman who was vomiting and in marked distress. The skin was dark tan, especially over the exposed parts. Some dark-gray pigmentation and stippling of the hard palate were noted. There were tachycardia and gallop rhythm at the apex. Examination was otherwise the same as on the first admission.

The blood pressure was 80 systolic, 70 diastolic. The temperature was 98.6°F., the pulse 110, and the respirations 20.

Examination of the blood showed a red-cell count of 4,400,000, with 12 gm. of hemoglobin. The white-cell count was 9200, with 55 per cent. neutrophils. The urine had a specific gravity of 1.018 and a pH of 5.0 and gave a +++ test for acetone; there were occasional hyaline casts. One stool was brown and guaiac positive. The blood chloride was 97 milliequiv. per liter, the sodium 125.2 milliequiv. The carbon dioxide combining power was 19.0 millimols per liter. The nonprotein nitrogen was 18 mg. per 100 cc., and the protein 6 gm. The van den Bergh was normal.

The patient was given 10 cc. of adrenocortical extract intramuscularly, followed by 20 cc. in 3000 cc. of 10 per cent dextrose in normal saline. In the next two or three days the blood chloride became 107.4 milliequiv. and the sodium 135.9 milliequiv. per liter. A diuresis test showed the volume of the night specimen to be larger than that of the morning specimen. On the fifth day the blood chloride was 101.7 milliequiv. per liter. The blood urea nitrogen was 5.6 mg. per 100 cc. The urine chloride was 116 milliequiv. per liter, and the urine urea 172 mg. per 100 cc. The daytime volume of urine was 130 cc., and the night volume 200 cc. She had three intramuscular injections of eschatin (adrenocortical extract) on the fourth, fifth and sixth hospital days, following which she improved considerably and the vomiting ceased. The stool was guaiac negative. A 17-ketosteroid assay showed an excretion of 2.8 mg. in twenty-four hours. The cephalin flocculation time was normal. The prothrombin time was 20 seconds (normal, 22 seconds). The hematocrit was 34.7. A spinal tap was normal. She was discharged on the seventeenth hospital day on an added salt intake (5 gm. daily).

Final admission (six days later). Following discharge she remained well for three days. She had no nausea, vomiting, fatigue or lethargy. On the fourth day she complained of tightness across the chest, which persisted. She had no pain, cough or weakness. The following night she could not

sleep because of a "feeling of impending disaster." Thirteen hours before entry the temperature was 101°F. She was listless and began to vomit. Throughout the day she became progressively weaker and extremely "tired." The temperature dropped to normal. One hour before admission the extremities turned blue, she was cold and clammy, the pulse could not be obtained, and she became stuporous.

Examination showed a cyanotic moribund patient with a spastic right arm held in flexion. She was frothing at the mouth, and the jaws were tightly clenched. She moved all extremities when stimulated. Respirations were shallow. The heart sounds could not be heard, and the pulse and blood pressure could not be obtained. Immediately after admission 25 cc. of Wilson's adrenocortical extract was given intravenously, along with 10 per cent of dextrose in saline. In fifteen minutes she became active. She was given oxygen and another 10 cc. of the extract intravenously, followed by a similar dose intramuscularly. She received about 1250 cc. of the dextrose solution in the course of two hours. At the end of that period she suddenly choked, frothed slightly at the mouth, gave a few gasps and stopped breathing.

DIFFERENTIAL DIAGNOSIS

DR. GEORGE W. THORN*: A thirty-three-year-old woman was first seen because of two positive Hinton tests, which were subsequently checked. Antisyphilitic treatment — two courses of bisinuth, one of Mapharsen and one of neoarsphenamine — was then instituted. At the end of a year she became jaundiced, was admitted to the hospital, stayed two months, went home for three months, came back for a relatively short period, went out again, returned and died. The questions are: Was syphilis the sole cause of her trouble? Were heavy metals the sole cause of her trouble? Did heavy metal intoxication complicate syphilitic infection? Was there some complication totally independent of heavy-metal therapy and syphilis?

The first point to take up is the jaundice. Jaundice as we know, occurs in approximately 1 to 2 per cent of patients with syphilis who are treated with arsenicals. It is about seven times as frequent in patients who are treated with arsenicals for syphilis as it is in patients with syphilis who do not receive arsenical treatment. In other words, there is seven times the chance of having jaundice due to heavy-metal therapy as compared with the possibility of jaundice on the basis of syphilis alone.

The jaundice reactions that occur in syphilitic patients with heavy-metal intoxication are interesting and can be placed in three groups. The first is the jaundice that immediately follows the *first injection* of neoarsphenamine, associated with a Jarisch-Herxheimer reaction. This type of jaun-

*Hearsey Professor of the Theory and Practice of Physic, Harvard Medical School, physician-in-chief, Peter Bent Brigham Hospital.

dice is usually not serious; it is transient and is supposedly due to the killing of large numbers of spirochetes. Another type of jaundice is that associated with "ninth-day erythema." In this reaction jaundice with chills and fever develops ten to twelve hours after the second or third injection of neoarsphenamine and it is quite readily diagnosed. It is not due to a hepatitis. In the majority of patients the jaundice disappears. This type has all the appearances and all the laboratory findings characteristic of obstructive jaundice. The phosphatase is over 10 Bodansky units, and the cholesterol over 250 mg.; the cephalin flocculation is low or negative. Hanger and Gutman¹ are responsible for describing this particular type of jaundice due to neoarsphenamine. It is different from the third type of jaundice or ordinary hepatitis, which one sees at any time during the course of neoarsphenamine, and which may occur as long as two, three or even four months following the cessation of heavy-metal therapy.

One other point before we embark on the chemical studies is the significance of the positive Hinton tests. We all know that false positives occasionally occur. One of the most illuminating pieces of information that has come out of the Army recently is that a primary take following smallpox vaccination is probably associated with one of the highest incidences of falsely positive Wassermann or Hinton reactions. From 10 to 20 per cent of persons develop a positive reaction after vaccination. One to two months later, however, the titer falls off and the reaction becomes negative. This is true of other infections that are associated with falsely positive serologic tests.

The important thing to me in a patient who has no physical evidence of syphilis and no history of primary or secondary disease is to be sure that the positive test represents syphilis. I think we can assume that it does in this case, because positive tests were recorded over some period of time. In the absence of a primary or secondary lesion, the Army and Navy follow a person with positive tests for a month or two before assuming that they are due to syphilis.

How much of this patient's illness may we attribute to heavy-metal therapy? What type of jaundice did she have? The ninth-day erythema, or the more frequent hepatitis? It is difficult to say. Certainly she did not give the characteristic picture of ninth-day erythema. Nausea and vomiting associated with jaundice suggest that she had some reaction in the liver to heavy-metal therapy. That is my first thought, and we have no evidence, as we go along, of any other disturbance that would cause jaundice except for the courses of bismuth. It is rather interesting that some patients treated with bismuth alone develop jaundice. In most cases, however, this occurs after ten or twelve injections, and may appear one or two weeks after the dis-

continuance of therapy. I suspect that this woman had a relatively mild degree of parenchymal involvement of the liver. One wonders whether the reaction was delayed, whether the patient was sensitive to the drug, or whether she had some underlying disease that gave her poor resistance to the injections. It is interesting that no jaundice developed until a second course of neoarsphenamine was given. We know that neoarsphenamine causes jaundice much more frequently than does Mapharsen, and logically, the addition of neoarsphenamine to the treatment may have been responsible for the jaundice.

Considerable interest centers around the serum chloride level of 83.6 milliequiv. per liter. What can produce that? Are low electrolytes caused by adrenal insufficiency? That is our problem. Did she have adrenal insufficiency before she was given treatment or did the toxicity of a heavy metal cause it? Of the patients with syphilis and Addison's disease, relatively few prove to have syphilis of the adrenal glands, although it is referred to in every textbook and article that I know of. Most reports discuss patients with symptoms of Addison's disease who, when given arsenical treatment, become asymptomatic, and it is concluded, without pathological data, that the patient had syphilis of the adrenal glands. In my experience, patients with Addison's disease do not tolerate antisyphilitic treatment, and I am quite convinced that this patient did not have Addison's disease at the time she was given the last injection of neoarsphenamine. I should expect such therapy to have induced collapse if she really had severe adrenal insufficiency.

If Addison's disease is not the cause of the disorder of sodium and chloride, what could have induced these changes? Low sodium and chloride can occur in patients who are vomiting and in patients who have a high concentration of organic acids in the blood, which is consistent with liver disease. The glucose tolerance test was normal, unlike that in patients with Addison's disease, when glucose absorption is disturbed.

The pigmentation is striking, but pigmentation is also typical of bismuth poisoning and helps us little in this difficult diagnosis.

She was given a vitamin K preparation. I do not know why the sodium acid phosphate was given. The jaundice improved, and she was discharged. For three months she had considerable craving for salt, and then was readmitted. She had had two colds or two upper respiratory infections, but she came back with a temperature of 98.6°F.—a patient with Addison's disease in moderate collapse has hypothermia. The pulse rate was 110. The patient was extremely weak and tired, which suggests possible myocardial change. The blood pressure was low. An interesting point is that while she was at home the blood chloride was 97 milliequiv., and the sodium 125 milliequiv. One

never sees this discrepancy in Addison's disease, and that is suggestive, if the chemical values are true, of a type of renal disease in which the chloride is retained in excess of sodium. If you give sodium chloride to a patient of this type you raise the sodium and chloride milliequivalent for milliequivalent. You will notice later that the chloride came up to 107 milliequiv. and the sodium to 135 milliequiv. I should say that a patient with Addison's disease associated with heavy-metal poisoning would not do well at home on salt, without hormone therapy.

There are two other features of great interest. She had free hydrochloric acid in the stomach. One rarely sees that in a patient with Addison's disease. The second point is that on the second admission there was a +++ test for acetone in the urine, which is rarely if ever seen in Addison's disease or in a severe liver disturbance. At that time, the van den Bergh was normal, the jaundice had disappeared, and she was given adrenocortical extract and intravenous glucose solution. Since 3 liters of glucose and saline solution was given with the extract, one cannot say that the latter was the effective agent. A Kepler-Power² water test was done. In adrenal insufficiency there is a tendency for the urea to be higher in the blood than in the urine. Patients with Addison's disease do not have good diuresis following water injection. The ketosteroids are interesting—they were low, but a good many patients have low ketosteroid excretion. If the ketosteroids are normal, one can immediately rule out Addison's disease. If low, in any patient who is hospitalized and sick, one cannot prove Addison's disease. The prothrombin time was normal. The cephalin flocculation test was normal. These constitute evidence against a severe grade of hepatitis.

The patient went home for two or three days, became listless, with a feeling of impending death, came to the hospital in extremis, had a temperature of 101°F. and died. Just before the final episode she became alert enough to respond when glucose and adrenocortical extract were given intravenously. That merely suggests, to my mind, the hydrating effects of glucose, especially a temporary improvement of the cerebral state so that she could realize where she was. Although there are a considerable number of points in favor of adrenal insufficiency, I hesitate to make that diagnosis in this patient because of several points: the presence of hydrochloric acid in the stomach, the +++ test for acetone in the urine and the disproportion between the chloride and sodium levels. The pigmentation is compatible, the excretion of ketosteroids is compatible, and the glucose-tolerance test and the clinical course fit in with many cases. I do not believe that she had Addison's disease before heavy metals were administered; if so, she would have had a much severer reaction.

Regarding hepatitis, I think that the patient had evidence of liver damage, but that it was not sufficient to cause death. She must have had a considerable amount of functioning liver tissue to have a +++ test for acetone in the urine.

Regarding the possibility of a renal lesion, arsenphenamine and bismuth might have caused it. There was evidence of tubular degeneration, but the final urine had a specific gravity of 1.018, with only a few casts. So far as the urine findings alone are concerned, one cannot say that she had nephrosis, but the response to sodium and chloride—the prompt rise in chloride and the slower drop in sodium—and the fact that the sodium chloride levels could be maintained on the intravenous fluid alone strongly suggest difficulty in sodium and chloride excretion on the part of the kidneys.

The blood pressure was low, and the pulse rate was rapid. I suppose that there were small areas of focal myocarditis and swelling of the myocardial muscle fibers. As a terminal event she may have had heart failure or even a pulmonary infarct. She had definite evidence of a terminal change in the brain, as demonstrated by the paralysis. I am a little disturbed with respect to the bone marrow. She may have had some depression of the bone marrow, because the final counts were lower than the earlier ones, but the bone-marrow depression was not marked.

Am I permitted to see the heart films? I should like to know whether the heart was small or normal.

DR. LAURENCE L. ROBBINS: It is certainly small, although many normal people have hearts of this size. This was taken in the Out Patient Department one year before the first admission.

DR. THORN: There was no subsequent change in the heart size?

DR. ROBBINS: No. The second film was taken three months before the first admission and showed no change. We have no later films.

DR. THORN: A small heart is consistent with adrenal insufficiency and certainly against extensive myocardial change, and against anything in the way of renal lesion. It almost makes me change my mind in this case.

If the heart became definitely larger, one would consider a myocardial or renal defect. If the heart remained small, one would certainly make a diagnosis of adrenal insufficiency. The heart size is one of the most important things to follow in a patient with adrenal insufficiency. One can tell more about the state of the circulation from the size of the heart than from any other factor. I must add to my diagnosis the question of Addison's disease.

DR. OLIVER COPE: In contrast to clinical observations, there is no change in the output of hydrochloric acid in the stomach in experimental adrenal insufficiency. In the surgical research laboratories of this hospital the dog has been observed to secrete hydrochloric acid (pH 0.88) throughout the development of acute adrenal insufficiency, even terminally.

It is, to my mind, entirely a matter of stimulation, which is difficult to obtain in the dog. The patient with Addison's disease also has anorexia and vomiting. When the dog is fed artificially by stomach tube it puts out hydrochloric acid even with a blood chloride level below 80 milliequiv. To my mind, therefore, the presence of hydrochloric acid in the stomach of a patient does not exclude adrenocortical insufficiency.

DR. JACOB LERMAN: When this patient was first admitted, the diagnosis was arsphenamine jaundice or hepatitis. The resident who saw her on various occasions, Dr. Gordon S. Myers, raised the question of Addison's disease because of the peculiar pigmentation in the mouth, plus the low salt in the blood. He thought that the appearance was different from that of bismuth poisoning. That argument went on pro and con between the residents, the interns and the visiting staff for some time, and finally the consensus was swayed against Addison's disease, primarily because of the presence of ketosteroids in the urine. The opinion was that any amount of ketosteroids militated against a diagnosis of Addison's disease.

I saw her when she came in the second time. The jaundice had cleared completely, and to me, the picture looked quite characteristic of Addison's disease, with a typical distribution of pigmentation. She was in collapse but responded readily to salt and adrenocortical extracts. We speculated whether bismuth poisoning can play a role in the production of Addison's disease. In the experience of a large syphilitic clinic where large doses of bismuth are given over many years it is extremely rare to find a case of Addison's disease. I therefore threw out bismuth as a factor.

We were particularly convinced of the diagnosis of Addison's disease when she returned in coma and died quickly. Because she had responded at first so quickly to small amounts of adrenocortical extract and of salt intravenously, we thought that she had a mild case of Addison's disease. The various members who saw her believed that the proper treatment was to carry her along on salt and to give extract as indicated. Apparently she was in a much severer stage of the disease than we had anticipated.

CLINICAL DIAGNOSIS

Addison's disease.

DR. THORN'S DIAGNOSES

Healed arsphenamine hepatitis.

Myocardial failure.

Pulmonary infarct.

Tubular changes in kidney (bismuth)?

Addison's disease?

ANATOMICAL DIAGNOSES

Addison's disease.

Tuberculosis of adrenals, bilateral.

Tuberculosis of mesenteric lymph nodes.
Pericarditis, acute fibrinous, with effusion.
Pulmonary edema.
Hydrothorax, bilateral.
Ascites.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: Autopsy showed that both adrenal glands were three to four times their normal size, and completely replaced by caseous tuberculosis. The regional nodes were caseous, and there was old tuberculosis in the lungs, both apices being completely scarred. The immediate cause of death was an acute pericarditis with effusion. It is perhaps fortunate for Dr. Thorn that chest films were not taken at the time of the last admission, because the effusion would have caused an enlarged heart shadow. The heart itself was extremely small.

DR. THORN: I have seen six cases of Addison's disease with pericarditis. In one or two of them it was hemorrhagic.

DR. COPE: In these cases was the etiologic agent a streptococcus?

DR. THORN: No cultures were done, and no organisms were seen on smear.

DR. CASTLEMAN: The liver was normal in size, perhaps a bit small, and showed no evidence of hepatitis. The kidneys were essentially normal. We found no anatomic lesions of syphilis.

DR. THORN: The acetone is the most interesting aspect of this case. It is unusual for the urine of a patient with adrenal insufficiency to give a ++++ test. Differential diagnosis could have been made on the response to desoxycorticosterone acetate rather than to sodium chloride, since the latter is nonspecific and helpful in many types of dehydration, whereas the hormone effect is specific.

CASE 30232

PRESENTATION OF CASE

A sixty-three-year-old night watchman entered the hospital because of cramps in the lower abdomen of five days' duration.

During the year preceding entry, the patient had noticed occasional cramps in the lower abdomen, increasing constipation without melena, slight decrease in the size of the stools and slight weight loss. Five days prior to admission he developed persistent cramps in the lower abdomen and anorexia. He had no bowel movements for the three days preceding entry, except for a small one on the morning of admission. During this time, however, he had

passed gas by rectum but had been aware of increasing retention of gas and distention

Physical examination showed a well-developed, slender man in no discomfort. The heart and lungs were normal. The abdomen was distended and tympanic. Intermittent, high-pitched, peristaltic rushes were heard. A large tympanic, nontender mass was present in the cecal area. Rectal examination

cecum was somewhat dilated. Proctoscopy, including the rectum and sigmoid to a point 20 cm above the anal sphincter, was negative.

On the second hospital day a cecostomy was done. Postoperatively the patient did well. On the third hospital day a barium enema showed a mass in the pelvis, displacing the rectum and sigmoid to the left. The examination was unsatisfactory because of the

FIGURE 1 Post-Evacuation Film following a Barium Enema
The small arrow points to the lesion in the sigmoid, the large arrow, to barium in the ileum

tion showed a soft palpable mass 7 cm above the anus

The blood pressure was 148 systolic, 72 diastolic. The temperature was 98.6°F, the pulse 100, and the respirations 24.

Examination of the blood showed a red-cell count of 4,480,000 and a white-cell count of 10,450. The urine was normal. A blood Hinton test was negative. The stools gave a ++ guaiac test. A plain film of the abdomen showed a large amount of gas in the colon, extending to the lower sigmoid. The

large amount of gas in the colon. A Miller-Abbott tube was passed. A repeat barium enema showed an annular area of narrowing, extending over a distance of approximately 6 cm, and situated about 3 cm proximal to the rectosigmoid junction. The margins were shelf-like, and there was ulceration. During fluoroscopic examination only a small amount of barium passed beyond the tumor. After the patient had evacuated some of the barium, the films showed that considerable barium had passed into the descending colon, and there was barium

in the small intestine (Fig. 1). A mass was present in the right side of the pelvis that displaced the rectum rather markedly to the left.

On the fourteenth hospital day a transverse colostomy was performed. This was opened two days later. There was excellent drainage. Irrigation to the loops was satisfactory. During the course of the next two weeks the patient's general condition improved considerably and he felt and looked much better. On the thirtieth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. E. PARKER HAYDEN: From the beginning this seems to be a typical story of progressive, large-bowel obstruction—a story of increasing constipation and cramps in the lower abdomen over a period of a year, with slight decrease in the size of the stools. The record states that no blood had been noted. One thinks naturally of the two commonest diseases that obstruct the large bowel in a person of this age: carcinoma and diverticulitis. The lack of blood makes one think of diverticulitis. On the other hand, this man had had a slight weight loss, suggesting cancer. There was also the five-day episode of pronounced obstruction, which brought about his entry to the hospital, and the period of three days in which he had had no movement except one small one, but was passing gas by rectum.

On physical examination the patient was described as being sallow, and he had a distended, tympanitic abdomen, with high-pitched peristalsis, suggesting an obstructing lesion based not on inflammation but on a mechanical obstruction somewhere in the colon. In diverticulitis there is, of course, a localized inflammatory process, but the resulting obstructive symptoms are mechanical in nature. There is blocking of the lumen, owing to swelling of the bowel segment, and a real mechanical obstruction develops. The finding that is most difficult to explain is the tympanitic nontender mass in the cecal area. I suppose we can fairly well rule out a distended bladder because of tympany and the location of the mass on the right side.

The first diagnosis that occurs to me in this case is an old appendiceal abscess with sufficient putrefaction in the abscess to produce gas. Now and then a large abscess is tympanitic to percussion, and it may not be tender if it has been present for a long while. On the other hand, since the man had no fever and no increased white-cell count, an abscess seems unlikely.

The man may have had some queer intraperitoneal herniation. I can recall a patient who would fit this description rather well. She had a herniation of the small bowel through an aperture around the cecum, producing a similar picture—a large, freely movable, tympanitic, soft mass in the right lower quadrant. I have never seen one since, but the

memory of this one came quickly to mind. This man could have had an intraperitoneal herniation. On the other hand, such a lesion would probably have involved the small bowel, and in that case one would expect symptoms of small-bowel, rather than large-bowel, obstruction. Furthermore, a Miller-Abbott tube was passed.

Another possible explanation is a volvulus of the right colon, which can produce a large tympanitic mass in that area. Yet we have evidence of a definite lesion in the upper sigmoid. If this lesion was 3 cm. proximal to the rectosigmoid junction, it should have been visualized when the proctoscope was passed 20 cm., but one must make allowances for a discrepancy in the estimated distance.

The description of the barium-enema examination, which showed a constricting lesion with shelf-like margins and ulceration, makes it difficult to conclude that this was anything except carcinoma of the descending colon. If there was a carcinoma of the descending colon, this, rather than the appendix, could have perforated and could have produced a big abscess.

One should also consider the possibility of some sort of cyst in the right lower quadrant or pelvis. In other words, the cecal mass may be one of the familiar red herrings that crop up so often in these conferences, and that have nothing to do with the principal diagnosis.

I shall conclude by saying that this woman had a carcinoma of the descending colon. This seems evident from the x-ray description and from what we know about the operative procedures. When one does a cecostomy, it is usually for large-bowel obstruction, although I have seen the operation performed when that did not exist. A transverse colostomy, coming later, suggests that the operator found something in the left colon which he thought he could resect, with an anastomosis. So, influenced by these facts, I think I must make a diagnosis of carcinoma of the descending colon, with acute obstruction of five days' duration. I have no idea what the soft mass was. The diagnosis that fits this picture best is some type of intraperitoneal herniation.

DR. BENJAMIN CASTLEMAN: Would you like to see the x-ray films?

DR. HAYDEN: Yes.

DR. MILFORD SCHULZ: The most pertinent ones were made following cecostomy.

DR. HAYDEN: I intended to emphasize the fact that, since the Miller-Abbott tube was used, obstruction in the small bowel seems likely.

DR. SCHULZ: Curiously enough the lesion shows best in the routine films rather than in the spot films. There is something peculiar down here. There are several collections of barium that do not seem to be in the colon.

DR. HAYDEN: That suggests perforation, with a large abscess cavity and gas.

CLINICAL DIAGNOSIS

Carcinoma of sigmoid, with ileocolic fistula.

DR. HAYDEN'S DIAGNOSIS

Carcinoma of descending colon, with obstruction and perforation.

Intraperitoneal small-bowel hernia?

ANATOMICAL DIAGNOSIS

Adenocarcinoma (Grade III) of sigmoid, with ileosigmoidal fistula.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: At operation the surgeon felt a large mass in the region of the descending colon that was adherent to loops of small bowel. He was able to separate a few of the loops of small bowel from the mass, but suspecting an ileocolic fistula because of the presence of barium in the small intestine as demonstrated by the x-ray films, he resected the colon and the adjacent small intestine.

We found an annular, 5-cm., ulcerating carcinoma of the sigmoid, which had extended through the serosa and communicated with the ileum by means of a fistulous tract 1.5 cm. long and about 2 mm. in diameter. No cancer was present in the small intestine.

ONE HUNDRED AND SIXTY-THIRD ANNIVERSARY

THE one hundred and sixty-third anniversary of the Massachusetts Medical Society, held at the Hotel Statler, Boston, on May 22, 23 and 24, proved to be the most successful meeting ever held. Although the total registration — 1440 — was somewhat less than the 1556 members who attended in 1942, it is obvious that the former figure represents a higher percentage of members practicing within the Commonwealth than does the number of two years ago, owing to the absence of approximately 1500 members because of military service.

At the annual meeting of the Council, several matters of general interest were discussed, and appropriate action was taken. The Committee on Membership submitted an exhaustive report covering the admission of graduates of foreign medical schools to the Society; on the basis of this study, the committee stated that no change in the by-laws was indicated, and this recommendation was approved by the Council. The Subcommittee to Meet with the Medical Advisory Committee of the Industrial Accident Board reported that arrangements had been made with insurance companies whereby physicians will be reimbursed for emergency medical care and that it is permissible for a patient to be moved to another hospital where he can be cared for by a physician of his own choice, provided there is assurance that the care will be adequate. The War Participation Committee stated that a program designed to take care of any catastrophic emergency — war or civilian — had been worked out as a co-operative venture by the Society, the American Red Cross and the Massachusetts Committee on Public Safety. After considerable discussion, it was voted to hold over the recommendations of the Postwar Loan Fund Committee until the February meeting of the Council, the consensus being that the reaction of the Society as a whole should be obtained before taking action. Dr. Reginald Fitz, Massachusetts chairman of the Procurement and Assignment Service, reported that approximately 2900 physicians coming under the jurisdiction of his committee were serving with the armed forces, that there had been little evidence of shortage of physicians, that the 9-9-9 plan for interns and residents was functioning satisfactorily and that, by and large, the medical manpower situation had become clarified and well adjusted. On the basis of recommendations by the Committee on a Medical Information Bureau, the Council voted to establish such a bureau at the headquarters of the Society, to appoint a committee to supervise the activities of the bureau and to appropriate the sum of \$2500 for the annual maintenance of the bureau. And, finally, the appointment of the Postwar Planning Committee was authorized. The officers elected for the current year are as follows: president, Elmer S. Bagnall; vice-president, Sumner H. Remick;

sident-elect, Reginald Fitz; secretary, Michael Tighe; treasurer, Eliot Hubbard, Jr.; assistant treasurer, Norman A. Welch; and orator, Frank H. Key.

At the annual meeting of the Society, Dr. William Robey presented an appreciation of the late treasurer, Charles S. Butler, and the president, Dr. I. Lee, reported on the state of the Society. At the close of the meeting, the orator, Joseph C. Key, delivered the annual oration, entitled "A Major Factor in Experimental Traumatic Shock," which will appear in a subsequent issue of the Journal.

The annual dinner was well attended, nearly 500 tickets having been sold. The Honorable Leverett Stanshall, Governor of Massachusetts, took the session somewhat to task for its failure to make laymen aware of all that physicians have done and are doing for the public good; he warned that methods to provide good medical care at a reasonable cost must be provided. Bill Cunningham, with his customary forceful style, pleaded for better morale at the home front.

Many excellent papers were presented at the several scientific sessions, and the Shattuck Lecture given by Dr. Alfred Blalock, surgeon-in-chief, at Hopkins Hospital, and professor of surgery, at Hopkins University School of Medicine, the paper being "A Consideration of Certain Recent Advances in Surgery."

The luncheon meetings of the sections were extremely popular; in fact at that of the Section of Medicine the demand to hear the speaker, Dr. Peter C. Alvarez, of the Mayo Clinic, was so great that the meeting had to be moved from Parlor B to the Georgian Room.

The scientific and technical exhibits were so numerous that the Mezzanine, as well as the Ballroom and Ballroom Assembly, was filled to capacity. Receipts from the rental of booths made an all-time record, a fact that will undoubtedly receive favorable comment from the Treasurer and the Committee on Finance.

Once again, the Society is greatly indebted to Gordon M. Morrison and his committee, as well as to Robert St. B. Boyd, the executive secretary.

NEWTON HEALTH DEPARTMENT AGAIN WINS AWARD

NEWTON has again received honors for attaining excellence in protecting public health in wartime by being one of the fifty-three cities and counties to receive recognition in the 1943 National Health Honor Roll. The program was sponsored by the United States Chamber of Commerce and the American Public Health Association.

The winners were selected by leading national authorities, who spent weeks grading the reports of participating communities throughout the country. Emphasis was placed on specific measures to control communicable diseases, such as venereal disease, tuberculosis and children's diseases. Sanitation, including protection of milk and food supplies, proper safeguards for maternity care, child health and welfare, effective health education, adequate measures to promote industrial health and other health services were also given primary consideration. Many of the participating communities were war-production centers that have found it necessary to make an inventory of health conditions regarding both wartime health problems and postwar planning.

In commending the winning communities as well as those that participated in the program, the United States Chamber of Commerce said:

This achievement deserves the highest praise and support and reflects great credit on the health officers, officials, voluntary health organizations, chambers of commerce and other business and civic groups in these localities for giving adequate attention to the wartime health of war workers and citizens.

It is our hope that the records of the 1943 National Health Honor Roll cities and communities will be an incentive and guide to others to build up their health protection services. We hold this an essential home-front contribution to speed the winning of the war and to meet the great problems of postwar readjustment.

The evaluation schedule used in this national program is one of the best possible tools for post-war planning. Its use gives every community exact knowledge of where it stands in health and hospital facilities in connection with adjusting itself to post-war conditions. Communities that make this inventory now are steps ahead of other communities in postwar planning. Armed with definite plans for improvements and expansion, these communities will obviously be in the best position to obtain trained technicians and additional facilities for improving their health programs after the war.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

COOK — Edward M. Cook, M.D., of York Harbor, Maine, died May 20. He was in his forty-sixth year. Dr. Cook received his degree from Tufts College Medical School in 1924. He was a member of the American Medical Association.

His widow, his mother and a son survive.

FLAGG — Harry H. Flagg, M.D., of Charlestown, died May 25. He was in his sixty-fourth year.

Dr. Flagg received his degree from Tufts College Medical School in 1908. He was a member of the American Medical Association and the Charlestown Medical Society.

His widow and two daughters survive.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

REGULATIONS REGARDING GONORRHEA REVISED

The regulations of the Massachusetts Department of Public Health regarding venereal diseases have recently been revised. Among other changes the regulations have been made applicable to chaneroid, granuloma inguinale and lymphogranuloma venereum.

One other change has been the adding of a new paragraph, which reads as follows:

Minimum Requirement for a Negative Diagnosis in Women Who Are Suspected of Having a Gonococcal Infection. Whenever a female is alleged to have been exposed to gonorrhea, or to have been the source of infection of gonorrhea, the department shall require that there be one or more negative cultures of material taken from the urethra and cervical canal, in accordance with the instructions accompanying the outfit, before the department will accept a report that the person is free from infection; said cultures to be done in a laboratory approved by the department.

(NOTE. If, in the physician's judgment, there exists a history of exposure and/or physical signs and symptoms of the disease in the female, regardless of negative laboratory findings, the case should be reported as gonorrhea.)

COMMUNICABLE DISEASES IN MASSACHUSETTS FOR APRIL, 1944

COMMENT

Diphtheria showed a distinct downward tendency in April although running far ahead of the same month last year. The cases were almost entirely confined to the eastern end of the Commonwealth. Meningococcal meningitis, pleasingly enough, showed a figure less than half that of last April. But it was still nearly eight times the seven-year median.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from: Amherst, 1; total, 1.

Diphtheria was reported from: Boston, 7; Brockton, 1; Chelmsford, 1; Fitchburg, 2; Lawrence, 4; Lexington, 1; New Bedford, 1; Salem, 1; Somerville, 1; total, 19.

Encephalitis, infectious, was reported from: Longmeadow, 1; total, 1.

Malaria was reported from: Boston, 15; Camp Edwards, 10; Cushing General Hospital, 3; Fort Banks, 20; Fort Devens, 15; Fort Rodman, 3; Haverhill, 1; Swansea, 1; total, 68.

Meningitis, .. . reported from: Acton, 1; Adams, 1; And .. . 1; Ashland, 1; Boston, 12; Bridgewater, 1; Brockton, 1; Cambridge, 1; Camp Edwards, 2; Carver, 1; Charlton, 1; Chelmsford, 1; Easthampton, 1; Fall River, 2; Fort Devens, 1; Framingham, 1; Greenfield, 1; Lowell, 2; Marlboro, 1; Medford, 1; Newton, 1; North Attleboro, 1; Northampton, 1; Norton, 1; Plymouth, 1; Reading, 1; Salem, 1; Somerville, 1; Springfield, 1; Swansea, 1; Wakefield, 1; Waltham, 1; Watertown, 1; Webster, 1; Weymouth, 1; Winthrop, 1; Woburn, 2; Worcester, 1; total, 54.

Meningitis, Pfeiffer-bacillus, was reported from: Boston, 1; Brockton, 1; Framingham, 1; Peabody, 1; total, 4.

Meningitis, pneumococcal, was reported from: Holyoke, 1; Lynn, 1; Melrose, 1; Quincy, 1; Springfield, 1; Sutton, 1; Westport, 1; total, 7.

Meningitis, staphylococcal, was reported from: Boston, 1; total, 1.

Meningitis, streptococcal, was reported from: Boston, 2; total, 2.

Meningitis, other forms, was reported from: Rockland, 1; (leptomeningitis) Springfield, 1; (leptomeningitis) Somerville, 1; total, 3.

Meningitis, undetermined, was reported from: Boston, 1; Lowell, 1; Ludlow, 1; Norwell, 1; Paxton, 1; Springfield, 2; Worcester, 1; total, 8.

Salmonella infections were reported from: Boston, 1; Cambridge, 1; Newton, 3; total, 5.

Septic sore throat was reported from: Billerica, 2; Boston, 9; Camp Edwards, 1; Fall River, 1; Haverhill, 1; Hull, 1; Greenfield, 1; Mansfield, 1; Upton, 1; Williamstown, 2; total, 20.

Tetanus was reported from: Hanover, 1; total, 1.

Trichinosis was reported from: Concord, 3; Hadley, 1; total, 4.

Typhoid fever was reported from: Chicopee, 1; Melrose, 1; Quincy, 1; Springfield, 1; total, 4.

Undulant fever was reported from: Cushing General Hospital, 1; Hopedale, 1; Millbury, 1; total, 3.

MISCELLANY

INTRAPLEURAL PNEUMONOLYSIS

The emphasis on early diagnosis of pulmonary tuberculosis would seem to be wasted if effective treatment is unnecessarily postponed. Discreminating selection of cases for collapse therapy, skillful choosing of the appropriate method and prompt employment of the elected procedure are indicated in the interest of all concerned. Pertinent facts are brought out in a recent article (Dailey, J. E. Intrapleural pneumonolysis. *Dis. of Chest* 9: 492-495, 1943), which is abstracted below:

It seems generally agreed that at least half the cases of pulmonary tuberculosis require some form of collapse treatment, either reversible or irreversible. Thoracoplasty is the best surgical example of the latter, while the oldest technic devised — pneumothorax — is a good representative of temporary, reversible collapse of the lung.

The chest specialist is the one to select either method after has evaluated the patient's condition and the stage of his tuberculosis. The mistaken belief that "time heals everything" must give way to acknowledgment that this disease invariably demands immediate consideration and active methods of treatment whenever indicated. In this race against time, the presence of a cavity calls for measures to avert it before delay invites a hemorrhage or spread of the disease in a hopeless condition.

Pneumothorax remains the first choice, but is successful only about half the cases in which it is initially tried. Lack of success may be attributed to adherence of the two pleural faces to that collapse of the cavity is impossible or incomplete. Delay in the institution of pneumothorax may be the parenchymal inflammation to progress and involve the pleura until adhesions form and so defeat later attempts what should have been a simple collapse procedure.

Formerly, a risky method attempted to stretch or break adhesions by forcing air into the pleural cavity under positive pressures. Serious complications developed if the person breaking off near the lung, tore the latter so that a septic or mixed infection empyema resulted. Serious hemorrhage might follow rupture of a sizeable vessel incorporated in the adhesion. Precious time was often wasted while the hoped for stretching of the adhesion was awaited, meanwhile the still unaffected cavity might supply bacilli to the other cavities elsewhere.

Intrapleural pneumonolysis was designed to transform, if feasible a poor pneumothorax result into a satisfactory effective collapse. Under local procaine infiltration anesthesia a special cannula is introduced between the ribs of the pleural space, transmitting a visual instrument not like a cystoscope. Through this the operator views the error and by means of a cautery inserted through a second cannula in another interspace severs the adhesions under direct vision.

Adhesions vary in size and shape and may be multiple, range from "fiddle strings" to short, thick and cylindrical, may resemble accordion-pleated sheets that radiate in directions and run all the way from paper-thinness up to one or several centimeters in diameter. In using the cautery it is necessary to remember that thicker adhesions contain lung tissue or large blood vessels and that they are attached firmly to the aorta, subclavian artery or other mediastinal structures. Great skill is required to avoid injuries similar to those already listed above as chargeable stretching and rupture of adhesions.

A skilled operator severs an adhesion as near its parietal extremity as possible, thus protecting the lung while exercising due caution as regards the intercostal structures as well, precisely if actual dissection in the latter area proves necessary. In competent hands backed by adequate experience and judgment when and where not to cut the operation is a minimal one as regards the patient's discomfort. In less experienced hands, however, it can present dangers exceeding those of almost any other major intrathoracic surgical procedure.

When a pneumothorax is started and adhesions can be seen to interfere with collapse, provided the space is large enough for the surgeon to manipulate his instruments, there is no reason for delay. Besides the well known hazards of an pneumothorax, the longer one waits the thicker grows the pleura, strengthening the bands and the greater the difficulty of cutting them.

Very large adhesions are often partially at periods of three or four weeks, widespread to the unsuccessful.

Pneumothorax and the selection at once of a collapse procedure other than pneumonolysis.

Summary. Remember the time factor and begin active pneumothorax treatment immediately in any patient who has a cavity. Don't wait to see what happens to the case with prolonged bed rest. Too often the realization will be accomplished by disappointment and chagrin.

In about half the cases a pneumothorax will be complicated by adhesions.

Don't attempt to stretch adhesions by means of a positive pressure pneumothorax.

Make an attempt to sever them by intrapleural pneumonolysis—again remembering the importance of time—as soon as possible.

In the hands of an expert, the unfavorable consequences of the operation are insignificant and the complications rare, but when performed by one with little experience, the dangers are very real.

If it is impossible to improve the collapse by pneumonolysis, abandon the pneumothorax and perform a thoracoplasty. — Reprinted from *Tuberculosis Abstracts* (May, 1944).

NOTE

Several appointments to the faculty of Tufts College Medical School have been recently announced. Dr. Norman A. Welch, physician in chief at the Carney Hospital, was named professor of clinical medicine. Mr. Manfred Bourditch, director of the Division of Occupational Hygiene, Massachusetts Department of Labor and Industries was appointed professor of industrial hygiene. Dr. Walter T. Garfield was designated as emeritus professor of dermatology, with Dr. John G. Downing, physician in chief of diseases of the skin, Boston City Hospital succeeding him. Dr. Raymond D. Adams, neuropathologist at the Boston City Hospital was named lecturer in neurology.

CORRESPONDENCE

RESTORATION OF LICENSE

To the Editor. At a meeting of the Board of Registration in Medicine held May 17, the Board voted to restore the license to practice medicine in this Commonwealth of Dr. David S. Goodman, 168 Chestnut Street, Chelsea.

H. QUIMBY GALLUP, M.D., Secretary
Board of Registration in Medicine

State House
Boston

ELIGIBILITY FOR NAVAL MEDICAL OFFICERS

To the Editor. A total of 100 qualified physicians and dentists are needed by the Bureau of Medicine and Surgery for assignment to the United States Veterans Administration. The program is open to males not over sixty years of age. Except for those specially nominated by the United States Veterans Administration rank will be comparable with age and experience. The physical requirements are the same as those established for general appointments, but special waivers may be granted. No indoctrination period is required. Those selected will be assigned to the United States Veterans Administration and physicians and dentists now thus employed will be assigned, if commissioned, to the Veterans Administration.

It is to be emphasized that the procurement of physicians and dentists for regular service in the Navy is still urgent. Recommendation for this special program will be given only in those cases in which a doctor or dentist is over age, or where a waiver of physical defects not ordinarily granted is required.

As in the case of all medical and dental officer applications, a statement of availability by the Procurement and Assignment Service is required.

MEDICAL FEES IN RURAL VERMONT

To the Editor. A study of farm economics in Vermont has recently been published (Adams, T. M. *Prices Paid by Vermont Farmers for Goods and Services and Received by Them for Farm Products, 1790-1940, 11 Ages of Vermont Farm Labor, for Farm Products, 1790-1940*, Bulletin 507, University of Vermont 1790-1940 176 pp. Burlington, Vermont 1944). The sources are account books of individuals and business firms in various rural communities of the state. Vermont has the largest rural percentage of population of any state in New England. In 1940 66 per cent of the people of Vermont were in communities of less than 2,500 population whereas in Massachusetts only 11 per cent lived in rural areas, and in Rhode Island only 8 per cent.

Four fifths of the towns in the state were covered in the search for account books of individuals and business firms.

Four tons of such books and diaries were consulted. The compiler is a member of the faculty of the University of Vermont, and this study was accepted by Cornell University as a thesis for the degree of Doctor of Philosophy.

One of the one hundred and twenty-three lists of prices is that of medical fees from 1800 to 1940, for which a table with eight hundred and forty-six entries appears on pages 58-60. I have abbreviated this table to forty-five entries by taking only the decennial years and only the fees for three types of medical service, namely, an office call, a house visit by day within one mile and an obstetric delivery. The list is as follows:

DATE	OFFICE CALL	HOUSE VISIT	OBSTETRIC DELIVERY
1800		\$0.25	\$2.00
1810	\$0.30	0.45	2.00
1820	0.30	0.45	3.00
1830	0.28	0.41	2.83
1840	0.30	0.46	3.12
1850	0.42	0.50	3.00
1860	0.42	0.50	3.00
1870	0.67	0.83	5.00
1880	0.62	0.75	5.00
1890	0.56	0.81	5.00
1900	0.54	0.88	6.14
1910	0.72	1.20	9.75
1920	1.29	1.89	20.00
1930	1.34	2.03	22.44
1940	1.34	2.03	23.15

The table does not give an entry for an office call in 1800. Account books of physicians in eastern New York, which I possess, show that when the fee for a house visit was 25 cents in the early nineteenth century, the average fee for an office call was 18¾ cents. Assuming that the same relation held in neighboring Vermont, the total for the three services was \$2.44 in 1800. This total did not double until 1865, and it trebled in 1900. In 1905 the total became four times the original and in 1912 five times the original. In 1925 it first passed ten times the original, and in 1940 it was nearly eleven times what it was in 1800. It is evident that fees in rural medical practice in Vermont increased much more rapidly in the twentieth century than in the nineteenth century. No mileage was charged for a visit within one mile, but rural physicians were accustomed to charge mileage for professional visits at a distance of more than one mile. The rate in Vermont in 1800 was in accord with that in other northern states, being 10 cents per mile. In 1865 the rate became approximately 20 cents, in 1900 approximately 25 cents, in 1916 approximately 30 cents, and in 1925 approximately 35 cents. The fees did not include medicine during the greater part of the nineteenth century; pharmacies were rare except in cities, and the physician furnished the medicines for his patients, for which he made an additional and separate charge. The prices entered in the table are the average from the account books of physicians in each year. The number available varied but was enough to give a fair cross section.

Dover, New Hampshire

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

A Hundred Years of Medicine. By C. D. Haagensen, M.D.; and Wyndham E. B. Lloyd. 8°, cloth, 444 pp., with 42 illustrations. New York: Sheridan House, 1943. \$3.75.

This is a story of the medical discoveries of the past century, written in simple terms for the layman. The various diseases and conditions are considered individually, and the work of outstanding figures, such as Virchow, Semmelweis, Koch, Pasteur, Lister, Ehrlich, Röntgen, Halsted, Cushing, Banting, Minot and Domagk, are emphasized. A bibliography for students is to be found at the end of the work, and the text is well illustrated.

Blood Supply of the Visual Pathway. By Calvin M. Kershner, M.D., M.S. (ophth.). 8°, cloth, 160 pp., with 33 illustrations. Boston: Meador Publishing Company, 1943. \$3.00.

This small monograph attempts to gather together in one place in a systematic manner the essential facts displayed in a wide literature, so as to make the anatomical knowledge of value to the ophthalmologist. The work is divided into two parts. In the first, the general arterial supply and the general venous drainage are considered. In part two there are detailed descriptions of the blood supply and drainage of each section of the visual pathway.

Clinical Diagnosis by Laboratory Examinations. By John A. Kolmer, M.S., M.D., Dr.P.H., Sc.D., LL.D., L.H.D., professor of medicine, School of Medicine and School of Dentistry, Temple University, and director, Research Institute of Cutaneous Medicine. 8°, cloth, 1239 pp., with 75 illustrations. New York: D. Appleton-Century Company, 1943. \$8.00.

This new work aims to represent fully the clinical interpretations of laboratory examinations and their practical applications in the diagnosis of disease, with a special section on technical methods sufficient for meeting the needs of teaching clinical pathology to medical and dental students. It is divided into three parts: laboratory examinations, divided into twenty-one chapters; the practical applications of laboratory examinations in clinical diagnosis, consisting of twelve chapters; and the technics of laboratory examinations, divided into nine chapters.

Veterinary Bacteriology. By Ival A. Merchant, D.V.M., Ph.D., C.P.H., associate professor of veterinary bacteriology and hygiene, Iowa State College. Second edition. 8°, cloth, 640 pp., with 135 illustrations. Ames, Iowa: The Iowa State College Press, 1942. \$6.50.

The second edition of this book has not been extensively revised, because of the exigencies of wartime. The chapter on the genus *Streptococcus* has been changed more extensively than any other. The fact that the first edition was published in September, 1940, and the second edition in November, 1942, speaks well for the popularity of the work.

The Biochemistry of Malignant Tumors. By Kurt Stern, M.D.; and Robert Willheim, M.D., professor, University of Philippines, Manila. 8°, cloth, 951 pp. Brooklyn, N. Y.: Reference Press, 1943. \$12.00.

This special work attempts to cover the relation of cancer to chemistry in the broadest meaning of both words, based on a collection of literature as complete as possible. It is the first publication in English of a treatise on the subject. The arrangement of the material is in line with the general principles of biochemistry. The main emphasis has been placed on the work of the last twenty-five years, and the literature has been systematically covered until the end of 1941. In 1936 the authors published in Vienna a German work of the same character and this book is an amplification of that monograph. Most of the views expressed were formed during a period of more than ten years of joint experimental work in cancer research. Considering the work of others in the field of cancer research, the authors have endeavored to enumerate the facts and also to introduce a critical analysis.

White Blood Cell Differential Tables. By Theodore R. Waugh, M.D., C.M., pathologist-in-chief, Royal Victoria Hospital, associate professor of pathology, McGill University, and consulting pathologist, Montreal Homoeopathic Hospital, Montreal, Quebec. 12°, cloth, 126 pp. New York: D. Appleton-Century Company, Incorporated, 1943. \$1.60.

Ninety per cent of the space of this small pamphlet is given up to tables for computing rapidly from the differential percentages the number of each type of white blood cell per cubic millimeter of blood. The tables cover the numbers up to 10,000. Preceding the tables there are 15 pages of preliminary descriptive matter.

THE TREATMENT OF ANURIA*

CHARLES W. STYRON, M.D.,† and WYLAND F. LEADBETTER, M.D.‡

BOSTON

THE early determination of the etiology of urinary suppression is frequently lifesaving and successful therapy depends largely on clinical evaluation of a case in the first few hours of observation. Ordinary routine treatment should be altered to meet the features in a particular case. Though the division into medical and surgical problems is necessary and helpful, a more descriptive classification is that of obstructive and nonobstructive anuria. Cabot and Iber¹ define obstructive anuria as that due to obstruction of the passage of secreted urine, and nonobstructive anuria as that caused by parenchymal pathologic changes that interfere with secretion. For a more specific group, nonobstructive anuria may in turn be divided into anuria due to true parenchymal disease of the kidney and that due to extrarenal factors unassociated with the kidney itself. The following classification outlines the conditions most frequently encountered in urinary suppression.

- Obstructive anuria
 - A. Obstruction of vesical neck (carcinoma, calculi and prostatic hypertrophy)
 - B. Ureteral and renal obstruction (calculi, inflammatory strictures, crystals of sulfonamide drugs, intrinsic carcinoma of the urinary tract, extrinsic carcinoma of the pelvic organs and abdominal tumors, trauma and misplaced sutures)
- Nonobstructive anuria
 - A. Extrarenal disease (cardiac decompensation, intestinal obstruction, peritonitis, gastrointestinal hemorrhage, medical and surgical shock), dehydration and burns
 - B. Renal disease
 - 1. Primary parenchymal lesions (glomerular nephritis, pyelonephritis, nephrosclerosis, polycystic kidneys, toxemia of pregnancy, lipid nephrosis and amyloid disease)
 - 2. Poisons (mercury, lead, cantharides, phosphorus, turpentine and oxalic acid)
 - 3. Nephrotoxic agents (acid hematin deposition after transfusions, black-water fever, myohematin deposition after crushing injuries and tubular deposition of sulfonamide crystals)
 - 4. Hepatorenal syndrome
 - 5. Cortical necrosis
 - 6. Thrombosis of renal artery or embolism

DIFFERENTIAL DIAGNOSIS

A careful history-taking saves time otherwise spent in observation and unnecessary studies. This is particularly true in cases of obstructive anuria, usually preceded or accompanied by pain in the bladder, abdomen or regions of the kidney that points to the source of anuria. The significance of a history of stones, operations or infections associated with the genitourinary tract or of treatment of carcinoma of the cervix or bladder should be kept in mind. A history of drug consumption is easily overlooked. In cases that have been followed or are under treatment the etiology is usually easily ascertained, whereas in patients who present themselves in anuria, the history may be the only lead that one obtains.

Physical examination in many cases helps to supply the explanation. In the obstructive anurias the most frequently found abnormalities are prostatic disease in men and pelvic disease, such as carcinoma of the cervix or pelvic tumor, in women. Occasionally an abdominal tumor or enlarged tender kidneys are present.

Many of the nonobstructive anurias are quickly ruled in or out by physical examination. Vascular collapse due to loss of blood, coronary thrombosis, dehydration and diabetic coma are usually brought to light by examination. Emboluses lodging in the renal artery usually originate in the heart, where mural thromboses are formed owing to myocardial infarction, rheumatic heart disease or bacterial endocarditis, with or without ventricular fibrillation. The hepatorenal syndrome may develop without jaundice, but usually jaundice is present. In any patient who presents jaundice and anuria, this syndrome ought to be kept in mind. Cortical necrosis is most commonly found following pregnancy or as a result of trauma, although it has been known to occur after a minor operation. Electrolyte imbalance (retention or depletion of sodium chloride) may show itself in either edema or dehydration, but the imbalance is secondary to some other disease such as nephritis in retention or gastrointestinal disease with vomiting in depletion. The findings in

primary renal disease are well known and need no comment here.

Diagnosis may depend on accessory data. A plain abdominal x-ray film should always be made in obscure cases of anuria. Unsuspected calculi and abdominal or renal tumors may give the clue to the diagnosis. Occasionally an intravenous pyelogram gives valuable information at the onset of urinary suppression; it may be obtained with safety if the nonprotein nitrogen is not over 60 mg. per 100 cc. In general, intravenous pyelograms give little information when the nitrogen retention is above this figure. If the diagnosis is in doubt, one should not hesitate to obtain cystoscopic examination and retrograde pyelograms with Diodrast, Skioldan or Hippurin. Sodium iodide as a retrograde dye should not be used, since it is irritating. The risk of a skillfully performed procedure is slight when balanced against the precise information that one obtains. The need for retrograde pyelography is exemplified by the difficulty one may have in differentiating ureteral obstruction due to sulfonamides from tubular obstruction due to transfusion reactions occurring in a case under sulfanamide therapy.

The laboratory data of particular value are the composition of the urine, the levels of nonprotein nitrogen, protein, chloride, sodium and sugar in the serum or blood and the carbon dioxide combining power or content of the plasma. The most impressive finding in the urine is of course gross hematuria, but it is usually present when the diagnosis of the underlying disease is relatively simple—for example, tumors encroaching on and eroding the mucous membrane of the genitourinary tract or the presence of kidney stones. Hematuria is ordinarily absent preceding extrarenal anuria, although initial hemoglobinuria is sometimes seen. Primary parenchymal renal disease rarely exhibits gross hematuria. This is true also of poisons and nephrotoxic agents, where anuria is frequently preceded by hemoglobinuria and cortical necrosis. In 117 cases of renal infarction reported by Hoxie and Coggin² gross hematuria occurred in only 4 (3 per cent), whereas microscopic hematuria was observed in 35 (30 per cent). The value of white cells and casts in the absence of dehydration and of red cells at any time are evident. A nonprotein nitrogen level in excess of 40 mg. per 100 cc. is considered elevated and warrants a search for the etiology. Serum protein levels below 5 mg. are often accompanied by edema, sometimes associated with edema of the kidney, albuminuria and decreased kidney function. Sodium and chloride are lost in considerable amount in vomiting and result in dehydration (see discussion of Case 3). Retention of sodium chloride, as in primary renal disease, may further increase edema by causing retention of fluids. A sodium chloride level in whole blood exceeding or lower than 450 to 500 mg. bears consideration, in both the etiology and the treatment of renal failure.³ Anuria may be

present in diabetic acidosis when the carbon dioxide plasma content falls below 20 vol. per cent. Hyperglycemia without acidosis, except experimentally and in the rare cases in which intravenous glucose is indiscriminately administered in large amounts, does not cause anuria.

TREATMENT

Obstructive anurias are usually due to vesical or ureteral blockage. In obstruction of the vesical neck the processes are usually of long standing, and in such cases gradual decompression is desirable. During the preliminary decompression the general condition may be improved by transfusions and intravenous salt solutions, so that if operative procedures are later necessary they can be carried out with less risk. When ureteral obstruction is present catheterization of the ureters may relieve the obstruction. At times ureterostomy or nephrostomy is necessary as a temporary procedure to relieve obstruction and to allow the return of renal function. When conditions permit, removal or correction of the primary cause of obstruction may be done, as in ureteral blockage from carcinoma of the bladder. In general, even dangerously ill patients stand necessary procedures on the kidneys or ureter for relief of obstruction remarkably well, and improvement begins quickly with the onset of diuresis. It is not unusual for patients with a high nonprotein nitrogen (200 to 300 mg. per 100 cc.) and generalized edema to recover rapidly if the obstruction is acute and little chronic renal disease exists.

Postoperative care is principally a matter of the proper administration of fluids, guided in particular by frequent determinations of the nonprotein nitrogen and chloride. Occasionally peripheral vascular collapse occurs, following a genitourinary operation. At times this condition is puzzling and persistent and in spite of plasma or transfusions lasts for several days. In such cases active measures to combat shock must be unremitting, for if shock is long continued, degenerative tubular disease of the kidneys may result. A lowered serum protein level and anemia should be corrected by transfusions of whole blood or plasma. Low blood chloride level should be corrected by the giving of intravenous normal or hypertonic salt solution.

A frequent mistake in therapy is the aimless administration of intravenous fluid. Dehydration should be corrected rapidly, but fluid should not be given to the point of producing edema. The administration of fluids should be governed by the rate of renal excretion and by the level of the nonprotein nitrogen and chloride. If the chloride is normal in the presence of dehydration a 5 per cent dextrose solution in distilled water should be used. If excess fluid is given in the absence of renal excretion in older patients, the circulation may be embarrassed and may further interfere with restoration of renal function.

The nonobstructive anurias are more frequent than the obstructive. Of 78 cases collected by Ot and Iber¹ only 29 were due to obstruction of any outflow. In extrarenal anuria, the present complaint is usually not lack of urine but a group of symptoms that point to some other underlying cause, although Segal and Read² reported 2 cases of gastrointestinal perforation without symptoms other than anuria. In these cases the anuria served to obscure the true condition. Hemorrhage in the gastrointestinal tract, cardiac failure, uremic coma and dehydration from nausea, vomiting or diarrhea, however, are usually fairly obvious. Occasional development of severe oliguria or anuria in such cases may complicate the clinical picture, and certainly makes treatment more difficult. This secondary nitrogenous retention is so rare in such cases as to be the actual cause of the anuria.

In primary renal disease treatment produces less dramatic results. The various measures used to promote diuresis are well known. The administration of diuretics, together with a salt-free diet, and the giving of limited fluids in the presence of edema usually constitute the treatment. The most frequently encountered renal poison is bichloride of mercury. Early administration of sodium formaldehyde sulfoxalate may be helpful; otherwise supportive treatment is necessary. The early peripheral collapse seen in these patients may be prevented by the giving of intravenous salt solution, glucose solution or plasma. Usually within forty-eight hours there is nitrogen retention, sometimes associated with lowered chloride and diminished alkali reserve. Talbott and his associates³ suggest the use of alkali, since the effectiveness of sulfoxalate is thus enhanced and since the alkali reserve is partly depleted.

Nephrotoxic agents are not infrequently seen in hospital practice,⁴ where transfusions and sulfonamides are so widely employed. When hemolysis occurs as the result of transfusion reactions, acid uric acid is precipitated in the kidney tubules. Many workers advise the preliminary administration of sodium bicarbonate by mouth to assure an alkaline urine for prevention of this precipitation when hemolysis occurs. This is especially valuable when difficulty has been encountered in obtaining a perfect cross matching prior to transfusion. After such an accident occurs, the early administration of intravenous sodium bicarbonate or lactate may be lifesaving. Once precipitation occurs, little can be done. Even then, however, it is worth while to administer intravenous salt solution or sodium lactate to keep the uninvolved tubules functioning. As a rule the sulfonamides are crystallized in the tubules of the kidneys or in the ureters as well as in the tubules. In such cases catheterization and lavage of the ureters and pelvis are extremely satisfactory in dislodging the loosely conglomerated

crystalline deposits. The sulfonamides may cause hemolysis and produce the same train of events as that seen in hemolysis from transfusion reactions. During the present war occasional cases of kidney tubular obstruction have been seen following crushing injuries. This may be due to the deposition of myohemoglobin formed in the crushed muscles. It has been suggested that the tubular damage in these cases is of a chemical nature, and that the danger of renal failure in patients subjected to crushing injuries should be anticipated and prevented. The application of a tourniquet to the injured limb and re-establishment of circulation have been advised as soon as measures were taken to produce diuresis. Measures to prevent tissue breakdown, such as packing the extremity temporarily in ice, may be helpful. Alkalinization is suggested.⁷

The hepatorenal syndrome is still a poorly understood phenomenon. Nitrogen retention and even anuria are occasionally found in patients with liver disease, with or without jaundice. This syndrome should therefore be anticipated and thus prevented in cases with gall-bladder disease and primary liver disease.⁸ Every patient presenting himself for gall-bladder surgery should have a critical appraisal of renal function. Prevention of nitrogen retention may be managed by adequate fluids, if not by mouth then intravenously. The carbohydrate intake should not fall below 150 gm. in twenty-four hours.

Cortical necrosis of the kidneys is occasionally seen post partum and following severe — usually abdominal — trauma.^{9, 10} Previous writers have said that the disease is always fatal.

Thrombosis of the renal arteries with renal infarction is occasionally seen as the result of emboli from the left side of the heart. There is little to do when this occurs save to support the patient generally and to prevent shock.

Decapsulation has been advised for anuria due to transfusion reactions and in particular to bichloride poisoning. Talbott⁶ mentioned a case that one of us (W. F. L.) had an opportunity to follow and that gave evidence of the futility of decapsulation in restoring renal function after such reactions. On the fourth day of anuria the ureters were catheterized and the right kidney was decapsulated. A flow of urine began twenty-four hours after operation. No difference in urine volume was shown between the two kidneys. Six weeks later, when a normal urine volume and nonprotein nitrogen level were present, clearance tests with inulin and Diodrast were done with catheters in each kidney. There was no notable difference in function between the kidneys.

Several cases of urinary suppression have been encountered that illustrate points of interest in the management of anuria. Reports of these cases follow.

CASE 1. Anuria due to postoperative degenerative tubular changes. A 71-year-old man was admitted to the hospital with acute retention of urine that had been present for a few days. Prior to admission catheterization had been done and a large amount of urine withdrawn.

At physical examination the blood pressure was 150/70. The heart and lungs were normal. A right indirect inguinal hernia was present. A markedly enlarged (Grade 3), smooth, elastic prostate was present. There was penile hypospadias.

The patient was catheterized, and the small amount of urine present in the bladder was withdrawn. The urine showed a specific gravity of 1.023, a slight trace of albumin and no sugar. The sediment contained scattered white and red cells but no casts. The nonprotein nitrogen was 35 mg. per 100 cc. The hemoglobin was 93 per cent (Sahli), the red-cell count 4,940,000, and the white-cell count 17,000.

Cystoscopic examination revealed a markedly trabeculated bladder and large lateral prostatic lobes. Since the patient's general condition was excellent, and since it was thought that no improvement could be expected from continued catheter drainage, a perineal prostatectomy was done. Immediately after operation the patient's condition was good, but a few hours later a severe hemorrhage into the bladder occurred. Since the perineal bag and the urethral catheter could not be irrigated, a suprapubic cystostomy was done under local anesthesia, bleeding being controlled by a Hagner bag. The blood pressure fell to 60/40. Two transfusions of 500 cc. each were given, and the blood pressure gradually rose to 110/60 during the next 24 hours. On the 1st postoperative day, however, the blood pressure ranged from 80/40 to 90/60 despite the intravenous administration of glucose solution, normal saline solution and stimulants. For the next 4 days the systolic pressure remained below 120, and during the 5 days after operation there was practically no urinary secretion. The nonprotein nitrogen rose to 153 mg. on the 3rd postoperative day. During this time 14,000 cc. of 5 or 10 per cent glucose in normal saline solution or distilled water was given intravenously, and on one occasion 50 cc. of 50 per cent glucose was given without effect. Edema appeared. The hemoglobin dropped to 58 per cent, and the serum protein to 4.8 mg. per 100 cc. The urinary secretion was 900 cc. on the 5th postoperative day and between 1000 and 3100 cc. during the following week. Despite this apparent improvement the nonprotein nitrogen rose to 245 mg. On the 12th postoperative day the patient developed bronchopneumonia. Oliguria developed and was followed by coma, and death occurred on the 17th postoperative day. The carbon dioxide content of the plasma at one time reached 32 vol. per cent but did not go below this figure. The sodium chloride level remained within normal limits.

Post-mortem examination showed pneumonia of the left lower lobe, healing ischemic necrosis of the liver and acute tubular degeneration of the kidneys. There was marked dilatation of the kidney tubules, with some areas showing regeneration.

This patient stood the operation well. The serious secondary hemorrhage with prolonged shock seemed to be the cause of the renal failure. The blood pressure was below or barely at the secretory level for about twenty-four hours. One can assume on the basis of the microscopic study of the kidneys that there was no appreciable chronic renal disease and that therefore the anuria resulted from the continued low blood pressure, acute degenerative changes associated with ischemia, an acid-base disturbance of the blood or a transfusion reaction. On the basis of blood chemical findings an acid-base disturbance can be excluded. For a time the possibility of transfusion kidneys was considered, but this was ruled out by autopsy. It is concluded that an acute degenerative process of the tubular epithelium associated with or due to poor circulation resulting from continued low blood pressure was the mechanism that prevented prompt recovery of

kidney function after the initial anuria. Some chronic back-pressure changes may have played a part. The low specific gravity of the urine after operation tends to support the assumption that the tubules concentrated poorly. Death resulted from terminal pneumonia and circulatory failure, since kidney function was improving even after death seemed inevitable. The chief point of interest in the case is the cause of tubular degeneration.

How could this case have been treated better? Of course, the obvious answer in such cases is to prevent, or at least to recognize and arrest, hemorrhage before serious shock develops. Occasionally, as in this case, the bleeding is so sudden and profuse that much blood is lost in the bladder before it can be recognized and treatment instituted. The blood loss was extreme, because even after two transfusions the hemoglobin was only 58 per cent. More transfusions shortly after the first two or, still better, the administration of plasma instead of intravenous fluids might have prevented continued shock and kidney damage.

CASE 2. Anuria due to ureteral stones and a solitary kidney. A 52-year-old woman had a left nephrectomy performed by one of us (W. F. L.) in December, 1940, necessitated by a calculous pyelonephrosis. An intravenous pyelogram showed a normally functioning and appearing right kidney. The right ureter was not catheterized for fear of introducing infection. Owing to the patient's poor general condition the left ureter, which contained a large stone, was not removed. Because of persistent infection in the urine and pain in the left lower quadrant of the abdomen, the left ureter was removed in March, 1941. Up to that time the patient had had no symptoms referable to the right kidney. Following the ureterectomy she was given a course of sulfathiazole therapy. The urine became clear. She remained well until June 13, 1940, when she was seized with sudden, sharp pain in the left upper quadrant of the abdomen and the flank. This was followed by chills, fever, nausea and vomiting.

On admission to the hospital the temperature was 105°F., the pulse 124, and the respirations 28. There was generalized edema. The patient was irrational and obviously very ill. The lungs were clear. The heart sounds were rapid and weak but otherwise normal. The blood pressure varied between 75/40 and 50/25. The abdomen was distended, and muscle spasm and tenderness were present in the right upper quadrant and the flank. The kidney could not be palpated.

No urine was present in the bladder. The hemoglobin was 76 per cent, the red-cell count 4,030,000, and the white-cell count 12,700. The nonprotein nitrogen was 65 mg. per 100 cc., and the blood chloride level was 507 mg. per 100 cc. A plain abdominal x-ray film was relatively unsatisfactory owing to gas-filled intestines, but no calculi were visible.

It was obvious that the cause of anuria must be determined quickly, and accordingly a cystoscopy was done on the day of admission. A catheter passed quite easily to the level of the right kidney, but no urinary drainage took place. It was possible to inject 10 cc. of fluid through the catheter and to recover most of it, so that it was assumed that the eye of the catheter rested in the renal pelvis. The catheter was left in place during the night. Five per cent glucose solution was given intravenously and caffeine with sodium benzoate was used. The blood pressure remained at 60/40, and no urine was obtained by ureteral catheter or from the bladder.

The next day there was no improvement in the general condition. The nonprotein nitrogen was 92 mg. per 100 cc., the blood chloride 531 mg., and the carbon dioxide content of the plasma 40 vol. per cent. The cause of anuria was puzzling, but it was necessary to assume an obstruction, unless an unusual situation, such as cortical necrosis or occlusion of the renal artery and renal infarct, had occurred.

location of the kidney was therefore carried out under ether, oxygen and ether anesthesia. When the upper ureter was exposed, a group of small stones were palpated easily removed. The ureter below this level was exposed and found to be patent. A large catheter slipped into the renal pelvis, but no urine was obtained. The ureterostomy was well. A trans-ureterostomy injection

200 cc. of a 5 per cent glucose in saline solution was given. The state of shock persisted. No urine was secreted. Two centimeters of adrenocortical extract was given every 4 hours. The blood pressure quickly rose to 110/60 and 120/80. The adrenocortical extract was continued for 36 hours, during which time the blood pressure rose to 160/100, where it remained for several days, returning to the normal level of 135/80. Following the onset of urinary secretion 540 cc. was passed in the first 24 hours, 1800, 3300 and 3900 cc. on successive days. The non-protein nitrogen was normal 1 week after operation. Follow-up x-ray examination showed some hydronephrosis but no calculi. The ureterostomy catheter was removed on the

shock. In this case a preoperative diagnosis of calculi blocking the ureter was not made, but it could have easily been made with a pyeloureterogram. It was thought that the ureteral catheter had passed to the kidney pelvis and that therefore the cause of anuria was not obstruction. Exploration of the kidney seemed the only course and was fortunately successful. Although the patient's condition was poor, operation affected her but little. The continued state of shock was the obvious cause of anuria once the obstruction had been relieved. The usual methods for treatment of shock were of no avail. In this case adrenocortical extract used empirically seemed lifesaving, although one wonders what the course would have been if it had not been used. It should be noted that hypertension

TABLE 1. Summary of Data in Case 3.

3th postoperative day, and the wound was healed by the 1st day. The patient was discharged 23 days after operation and has since remained well.

There are several interesting points brought up by this case. What was the cause of the shock that made the case so difficult to treat? We do not recall a case of a blocked ureter by stone when the kidney involved was solitary or when the opposite kidney was normal with associated shock. In fact, one would suppose that a compensatory mechanism would produce hypertension. In a recent case similar to the one reported above in which anuria resulted from blockage of a solitary kidney by a stone at the ureteropelvic juncture, a compensatory hypertension was noted that disappeared when the stone was removed.

The cause of shock may have been pain, although in this case it was apparently not so severe as to cause shock. Toxemia from an acute infection may have been the cause, but a similar infection involving one or two kidneys would not likely result in

persisted for some days thereafter. After diuresis was well established, sulfathiazole in small doses was given, with prompt disappearance of the fever.

CASE 3. Anuria due to extrarenal azotemia. A 59-year-old woman had had diabetes mellitus for 9 years. Eight months prior to admission she had a small cerebral thrombosis, from which she recovered without noticeable residual. Following recovery she remained relatively well. The urine had been practically free of sugar on a diet without insulin.

During the 5 weeks before admission the patient felt generally weak and found it necessary to spend much of the time in bed. During this period she felt unable to do much for herself at home and received little care. She grew weaker, but had no definite symptoms until 5 days before admission, when she began to vomit. She did so four or five times a day, and as a result was able to take little fluid or food. She became sleepy and a little short of breath. There was some dizziness. The day before admission she developed weakness of the left arm and leg.

On admission the patient could scarcely be aroused. The pulse blood pressure was 90/70, the temperature 98°F., the pulse 120, and the respirations 28. The skin was loose and dry. The pupils were slightly irregular and myotic. The mucous membranes were dry. The nose and throat were clear, and the thyroid gland was normal. The heart was not enlarged; the rate was regular and no murmurs were heard. Numerous moist rales were heard throughout both lung fields. The

abdomen was soft, and no masses were felt. Arteriosclerosis of moderate degree was present. The left arm and left leg were flaccid, and clonus was present in the left arm.

The blood sugar level, the carbon dioxide combining power and the nonprotein nitrogen were tested and when the results were reported half an hour later the patient was given 10 units of crystalline insulin and 20 units of protamine insulin. A lumbar puncture showed the spinal fluid to be normal. The patient gradually recovered consciousness and continued to improve with the parenteral administration of normal saline solution, followed later by glucose solution (Table 1). The paralysis improved slightly. She was discharged from the hospital with no apparent residual except the paralysis.

The extreme dehydration, initiated by inadequate care at home and perpetuated later by nausea and vomiting, almost resulted in death. This case represents one of the most satisfactory of the extrarenal azotemia group. Although figures on the levels of sodium and chlorides are not available, it is certain

primary requisite in the treatment of such a case as this is the administration of saline solution. Glucose solution should be employed only when adequate replenishment of sodium and chlorides has occurred.

CASE 4. *Anuria due to extrarenal azotemia in the presence of chronic nephritis.* A 66-year-old woman was admitted to the hospital on February 3, 1941, in a comatose state. She was markedly dehydrated. One year prior to admission she had begun to have anorexia and loose, bloody, mucus-containing stools four or five times a day. She had lost about 25 pounds in weight. Six weeks prior to admission she was found to have a polyp of the sigmoid and was referred to the hospital for operation. During the 3 or 4 days prior to admission she had had a good deal of vomiting and had grown progressively weak.

On admission the blood pressure was 120/70. The eye-grounds were normal. Bilateral basal rales were heard in both lung fields. The heart was normal in size, but a harsh systolic murmur was heard over the entire precordium. A

that with five days of vomiting reduction in these electrolytes occurred. As Gamble¹¹⁻¹³ has shown, the electrolytes largely determine the volume of body fluids, and dehydration is a secondary phenomenon in an adjustment process whereby the osmotic pressure of the extracellular and intracellular fluids is kept in proper relation. The chlorides can be replaced in part by bicarbonate, but no source of intrinsic sodium is available and this substance must be replaced, when lost, from an extrinsic source. Ginsburg¹⁴ showed in his case that administration of fluids is not enough to ensure recovery. In fact, the administration of isotonic glucose solution alone may do harm through the production of a so-called "electrolytic vacuum" into which diffusion of sodium and chloride occurs, with further depletion of the body store. The nitrogen retention in such cases is secondary to peripheral circulatory failure, with reduction in effective glomerular filtration. The nonprotein nitrogen may be further increased by protein catabolism associated with starvation. It thus appears that the

tentative diagnosis of extrarenal azotemia was made. With the degree of dehydration as a result of diarrhea it was difficult to determine how much renal damage was present. Saline solution and 5 per cent glucose solution were repeatedly given intravenously. For the first 48 hours the patient's condition was unchanged, but thereafter she began to improve and continued to do so. Large amounts of mucus were passed by rectum, but despite the fact that the amount passed sometimes exceeded 1000 cc., it was possible to maintain an adequate degree of hydration.

Table 2 illustrates the changes that occurred in the urinary output, the nonprotein nitrogen, the phenolsulfonephthalein excretion, the serum chloride, the plasma carbon dioxide and the urine. Concomitant with the fall in nonprotein nitrogen, the hemoglobin level and the red-cell count also fell from 126 per cent and 6,670,000, respectively, on admission to 96 per cent and 4,640,000 on the 7th hospital day, when the nonprotein nitrogen reached its lowest level (63 mg. per 100 cc.).

On the 5th hospital day the patient was rational. She seemed strong and was able to take some fluid and food by mouth. It was thought at that time that she would continue to improve and that eventually she might be prepared for operation. However, the stationary phenolsulfonephthalein excretion and the drop in urinary output to 600 cc. were not taken into full account.

On the 7th day the patient had a slight fever, and on the following day she had a shaking chill. The latter was thought to be due to a urinary infection and she was given sulfathiazole. She received 11.3 gm. (170 gr.) in the ensuing

ours, but failed to improve. Oliguria became severe, the ureters were catheterized to be certain that no action was present as a result of chemotherapy. The patient lapsed into coma shortly thereafter, became anuric, died on the 11th day.

It was thought that sulfathiazole therapy might have had something to do with the secondary oliguria, but actually output decreased and the nonprotein nitrogen became anuria prior to the institution of sulfathiazole therapy.

Autopsy a large, fungating carcinoma of the rectosigmoid, measuring 12 cm. in diameter, was found. The cysts of the kidneys were granular and marked by numerous small, clear cysts. A number of shallow scars were present on each kidney surface. The aorta showed marked atherosclerosis, particularly in the abdominal portion. On microscopic examination cholesterol deposits were found in coronary arteries. The glomeruli of the kidneys showed considerable variation in size, and many were scarred and necrotic, a few being completely obliterated. There were areas where recent tubular degeneration had occurred.

This case illustrates the great changes that may occur in a patient with pre-existing renal disease when an extrarenal factor is superimposed. The patient may well have lived for some time had the ureters, which were already damaged, not had this as a burden to combat. This case affords a contrast to Case 3, in which the kidney function returned to normal and in which no chronic kidney disease was apparent.

Case 5. Anuria due to chronic glomerulonephritis. A 62-year-old woman had had diabetes mellitus for 6 years. She was first seen in 1939 when she had slight dyspnea on exertion, occasional cough. On physical examination the blood pressure was 170/80 and the weight 170 pounds. The heart enlarged to the anterior axillary line and a loud apical systolic murmur was heard. The lung fields were clear. Edema was present. The nonprotein nitrogen was 23 mg. per 100 cc. The urine showed a specific gravity of 1.007, a slight trace of albumin and no sugar. The sediment contained 2 to 3 white cells per high-power field. A phenolphthalein test showed excretions of 6, 12 and 33 cc. in $\frac{1}{2}$, 1 and 2 hours, respectively.

The patient was next seen on June 28, 1940, complaining of gradual loss of vision in the preceding 6 months. She was unable to read. The pupils were too small to permit ophthalmoscopic examination. The urine showed a specific gravity of 1.010 and 100 mg. of albumin. The sediment contained 8 to 10 hyaline casts or finely granular casts per high-power field, no blood and many white cells, both single and clumped.

The patient was next seen in March, 1941, when following severe cold 2 weeks previously she was found by her physician to have albuminuria. She began vomiting occasionally and noticed some swelling of the feet. Oliguria had been present several weeks before admission. At admission on March 22, the blood pressure was 172/92. The heart was enlarged to the left anterior axillary line, the rhythm was regular, and a severe systolic murmur was heard. There was no edema of the sacrum and of the lower extremities.

The urine showed a specific gravity of 1.020 and a normal reaction, with a slight trace of albumin and no casts. The sediment showed no casts, rare red blood cells and many white cells per high-power field. Later many white cells were found. The nonprotein nitrogen was 125 mg. per 100 cc. The patient was given 5 per cent glucose solution intravenously on several occasions. The urinary volume remained low, however, and the largest volume during a 24-hour period in 2 weeks' time was 300 cc., with a daily average of 100 cc. The nonprotein nitrogen gradually increased from 125 to 180 mg. over a period of 10 days in the hospital. Despite this, she remained fairly comfortable and capable up to the last 5 days of her illness. For the last 24 hours of her hospital course she was completely anuric.

Chemical data showed the serum protein to be 5.2 g. per 100 cc., the albumin-globulin ratio 0.68, and the blood chloride 100 mg. per 100 cc.

Autopsy showed chronic glomerular nephritis.

This case illustrates the relatively slow onset of symptoms from urinary suppression in patients with chronic nephritis. Although for a period of two weeks this patient had increasing suppression of urine, she did not feel sick enough to visit the hospital until this period of time had passed. This case is in contradistinction to the obstruction anurias, in which the course is stormy practically from the outset. The duration of life after the onset of anuria in cases of nephritis is usually less than a week. This is shorter than the duration of life after obstruction occurs, which is apparently due to the changes that have already taken place before stoppage of urine occurs. Kutzmann¹⁵ stresses the relative comfort of patients with primary renal disease.

Case 6. Anuria associated with obstructive jaundice. A 67-year-old woman first noted gas on the stomach in the evening, relieved by eructation, several months prior to admission. Shortly thereafter she developed cramps in the right upper quadrant of the abdomen lasting for 12 hours and followed the next day by chills, a temperature of 103°F. and clay-colored bowel movements. She entered the hospital with jaundice. The extent of jaundice was not reported, but she was known to have had clay-colored stools. Oral gall-bladder dye showed a nonfunctioning gall bladder. Within the course of 24 hours after admission suppression of urine gradually developed and the nonprotein nitrogen was found to be 82.5 mg. per 100 cc. The urine was positive for bile, with a slight trace of albumin. The sediment was negative.

The patient was given intravenous normal saline solution and glucose solution intravenously. There were 24 hours during which no urine was passed. The jaundice began to improve spontaneously, and associated with this urine was passed and there was a gradual decrease in the nitrogen retention.

Four days after treatment was started the nonprotein nitrogen had dropped to 60 mg. and 3 weeks later it was 17 mg.

The patient was first seen by us 3 months following this episode, with a complaint not directly related to the above. In the course of therapy, however, an intravenous pyelogram was done. This showed poor renal function on each side. The output of dye was not sufficient for adequate delineation of structures. There was no calcification. A phenolphthalein test showed excretions of 21, 8 and 10 per cent in $\frac{1}{2}$, 1 and 2 hours respectively. The urine had a specific gravity of 1.020, with a slight trace of albumin and no bile. The sediment showed 13 to 14 white cells per high-power field but no red cells or casts. The nonprotein nitrogen was 37 mg. per 100 cc. An electrocardiogram was normal.

This case illustrates the urinary suppression not uncommonly seen in patients who develop jaundice in the presence of pre-existing renal damage. Thompson, Frazier and Ravdin¹⁶ believe that in obstructive jaundice associated with evidence of poor renal function there usually exists a renal lesion that is complicated by cholemic nephrosis. They demonstrated a high incidence of glomerular lesions at autopsy, and these changes predominated in elderly patients. The main lesion associated with the hepatic disorders was dilatation and compression of the lining epithelium, with various secondary changes. These authors emphasize the necessity of care as regards the renal function in such cases, since the latter may be the determining factor in improvement. Bartlett¹⁷ mentions the rarity of nephritis associated with other diseases of the abdominal viscera.

The best treatment is prevention by adequate administration of fluids and early relief of jaundice. Essentially the treatment after oliguria has developed consists in the intravenous administration of glucose, at least 1500 cc. of 5 per cent solution daily, in an attempt to initiate diuresis. The blood sodium chloride level should be followed and kept within the normal limits of 450 to 500 mg. per 100 cc.

SUMMARY

The etiology, diagnosis and treatment of anuria are outlined.

The importance of frequent complete blood chemical determinations and the proper administration of fluids, as to both type and quantity, are emphasized. Excessive fluid by vein in anuria may be harmful, and when fluid is given the quality and quantity should be given consideration.

Six cases are discussed in detail. These illustrate various points in the management of anuria. It seems obvious that in most cases early treatment, in the absence of severe chronic renal disease, should result in recovery.

DR. SAUL TCHERNICHOVSKY, 1875-1943

A Hebrew Medical Poet Laureate

HARRY A. SAVITZ, M.D.*

BOSTON

A poet alone has the qualifications to represent worthily that which is great and heroic in a people.
— Maurice Maeterlinck.

DR. SAUL TCHERNICHOVSKY was a doctor of medicine by profession and practiced with distinction all through his life, but his fame rests on the fact that he was the uncrowned king of modern Hebrew poetry. For nearly half a century, Bialik and Tchernichovsky were the renowned Hebrew poets. During the last decade, the laurels of the so-called "Hebrew poet laureate" were worn by Dr. Tchernichovsky.

The Hebrew poet laureate holds no official position, nor does he receive even the minimal salary of the British poet laureate, that of a barrel of wine and £120 a year. But his dignity and honor are none the less, and perhaps even more. The Hebrew poet laureate is neither appointed nor elected. But instinctively there is a feeling among his fellowmen that he is "the" poet. Somehow they sense that he is their spokesman; his views express their remote hopes, as well as their present sorrows. It appears as though his pen were dipped in their blood and that he more than any other reveals to the world their innermost woes and pangs, as well as their

*Instructor in medicine, Tufts College Medical School, and junior visiting physician, Beth Israel Hospital.

aspirations and hopes. His poetry may symbolize the very period they are living in, and speaks the language that is so typically their own. On reading this poetry one experiences the feeling that it is what he himself would have said had he the ability to so express it. "Such a poet was Bialik. He symbolized the Hebrew Renaissance with all its complexities. On the other hand, a poet may in a sense be the reincarnation of a period in the past history of a people and so remind them of their forgotten historical task. He may speak a language to which they are not accustomed, yet the people feel in these poetic creations the echoes and reverberations of their poets and prophets. Such a poet was Dr. Tchernichovsky. So when the great poet laureate of the Jewish people, Chaim Nachman Bialik, died in 1934, the laurel, so to speak, was placed on the head of Dr. Tchernichovsky, and he held it with dignity until his death on October 14, 1943. For in his poetry his people finally found the revival of their national instincts and historic trends. He portrayed to the world their heroic past. They felt about him what Maurice Maeterlinck said of the great Belgian poet, Emile Verhaeren, "A poet alone has the qualifications to represent worthily that which is great and heroic in a people."

But he was more than a poet whose works were read for mere entertainment. He was his people's physician, so to speak. He tried to give them a new outlook on life and to stimulate and develop their springs of emotion, rather than their intellectual resources. He tried to focus their attention to the

Let us unfold the story of this doctor and poet. Tchernichovsky was born on August 20, 1875, in Russia, in the village of Michailovka on the Ukrainian border. This is a country that is well known for the severity of its winters and its burning summers — a vast country in which there is nothing

SAUL TCHERNICHOVSKY
1875-1913

stream of life and to attune their ears to the multitude of harmonious vibrations in nature. Turning to the early history of his nation, he tried to arouse their ancient instincts for life. He tapped all sources and channels of many peoples and tongues, wherever beauty and life were found. So he recreated in Hebrew the classics of various nations. In so doing he reversed the process, for he brought his skill and ability, a poet for all humani-

mild or temperate, a land where the cold blasts from the Arctic Ocean sweep down over great stretches of land uninterrupted until stopped by some mountain chain. These scenic and atmospheric conditions made an indelible impression on the young poet's mind and mood. They became his inheritance for the rest of his life. As

He continues to describe how he spun his dreams in the image and model of his native land. For there he met the eternal wanderer — you will never guess his name — why, the Wind! He often carried dark leaden clouds and at times just played wildly in God's open spaces — a frolic in treasures of ice and snow. There he heard the shrieks of the wild eagle.

Such was also his fate, the poet concludes. Like the eagle's call, he was often misunderstood, and like the Wind, he wandered from place to place.

Tchernichovsky's personality and works also reveal dominant hereditary traits. He came of a stock of rugged people, physically strong and intellectually curious. His ancestors participated in Russia's wars and survived various persecutions. His great-grandfather lived long enough to celebrate a second confirmation (Bar Mitzvah), for he lived one hundred and thirteen years. His mother's father, Saul Karp, after whom he was named, was a cultured and widely traveled man. He mastered the French, Italian and Russian languages. He translated Ukrainian folk songs into Hebrew and then sang them in their original melodies. Several members of his family participated in the Caucasian wars. His father was a righteous and observant Jew. His mother was a cultured and sensitive lady. Her sister was one of the first women to matriculate in a Russian university. As a student, she was attracted to the revolutionary movement and was exiled to Siberia. It was this aunt who started to teach Russian to young Saul when he was but five years old. Two years later, his father began to teach him Hebrew through the medium of Russian. It is told that in order to commit the Hebrew alphabet to memory, young Saul made models of the Hebrew letters with dough and baked them. These alphabet cookies were the joy of the young lad. This is extremely symbolic, for during the rest of his life he succeeded in modeling many a literary dessert out of the alphabets and legends of various nations. He was then prepared for the source book of Hebrew literature, — the Bible, — which he mastered in its original tongue, and this became part of his being. He was also introduced to the modern Hebrew writers and poets, such as Mapu, Lebenson, Dolitsky and Manne. At the age of twelve, he wrote his first poem, "Uriah, the Hittite," which he illustrated artistically himself. But nothing was preserved of his juvenilia. He was a profuse reader and he continued to study Russian literature in its original and translated works.

In 1890, Tchernichovsky went to Odessa and entered the Commercial High School. There he came in contact with a group of men of great vitality — men whose culture was universal. They were dreamers, men of vision, who tried to forge a new dawn and a new freedom. They were the early "Lovers of Zion." This circle of friends made a lasting impression on the youthful student. It was

while he was in Odessa that his first Hebrew poem, "Bahalomi" ("In My Dream"), came off the press. It appeared in a Hebrew journal, *Ha-Pisgah*, published in Baltimore, Maryland, in 1893.

In 1896, Tchernichovsky was graduated with distinction from that school. During these years he acquired a working knowledge of the English, German and French languages. He had a rare gift for languages. Not only was he able, in a short time, to read and study their literatures in the original, but he was able to utilize these languages in his poetic creations. Thus in 1897 he began his translation of *Hiawatha* by Longfellow, which he rendered in lasting biblical verse.

To be fully prepared for his career of a physician, he had to study Greek and Latin. Here again, he was riding Pegasus on his way to medical school. For in 1896 he started to translate the poems of Anacreon from Greek into Hebrew.

In 1898, Tchernichovsky's first collection of poems was published in Warsaw. It was called *Hezionoth Umanginoth (Visions and Melodies)*. At first, most of the critics were harsh and severe. They were dazzled by this poetry's newness. Here was an outburst of feeling, an explosion of strength. Here were new visions, new melodies. Words were used in new combinations and new arrangements. Here was no stream of old quotations, but words to portray certain moods. The critics did not at first grasp the meaning. Were not our own critics dazzled when Walt Whitman first appeared on the American scene? Here, too, was a prophet and poet who exulted in the new strength and life of America. These fountains of poetry do not necessarily follow the old patterns. So it is strange at first. Yet one writer immediately saw this poetry's merit. Reuben Brainin (1862–1939) was the leading Hebrew critic, essayist and biographer, as well as a writer of beautiful lucid Hebrew. In his introduction to Tchernichovsky's first edition, he exclaims: "Here is indeed a poet who is treading a new path. His muse does not appear in borrowed clothes — to be sure, its wings are young and tender, but there are no foreign feathers on them."

In 1899, Tchernichovsky matriculated in the Medical Department of the University of Heidelberg, and spent four years there until 1903. To broaden his general knowledge, he also studied philosophy for the first two years under Professor Kuno Fischer. He also studied the history of religions. Meanwhile he acquired the knowledge of another language — Italian. Although steeped in medical studies, he never forgot his first love — poetry. This is also true of his entire medical career, which he never abandoned. He may have courted Erato (goddess of lyric and love poetry) for a while and then started to flirt with Calliope, but he never abandoned Minerva. There was no jealousy among the goddesses. On the contrary, as we shall see, his medical study influenced his

poetry, while his poetic sensitivity was revealed in his medical practice. So as a student in Heidelberg he published some of his finest poems, among them "Before the Statue of Apollo," "Baruch of Mayence" and "At the Sea."

The next four years, from 1903 on, we find Tchernichovsky in Lausanne, Switzerland, where

served as assistant in the Royal Institute of Medicine.

During World War I, Tchernichovsky enlisted in the Russian army, serving with distinction from 1915 to 1918. Here the poet of love, life and sunshine became the beloved physician of the ill, wounded and maimed. He saw service in a mili-

An Autographed Title Page of the First Edition of the First Book of Poetry by Tchernichovsky.

received his M.D. degree in 1907. On the completion of his medical studies, he returned to his native land, Russia. For the next three years (1907 to 1910), he served as a physician for the *Zemstvo* (the local town government) in the province of Larkov. There he practiced among the Russian peasants with great success. In 1907, he was arrested in Melitopol, charged with a political offense, but was fortunately released after six weeks of imprisonment. During the next four years he was active in medical work in St. Petersburg, where he

tary hospital and received a medal on discharge, as well as other testimonials, including a Hebrew Bible. Many letters of appreciation by soldiers of the White and Red armies were published in the newspapers. After the war he returned to Petrograd, where he served in another military hospital as assistant director of the Department of Sanitation and Statistics for the Red Cross. When the Bolsheviks came into power, he was sent on a special mission to the Crimea. Up to 1922, he was, in Odessa, as a physician in various military hos-

That year he went to Berlin, where he lived for several years.

During all these years that Tchernichovsky practiced medicine, he suffered hardships, but his creative activity never ceased. At this time he was engaged in the translation of the *Iliad* and *Odyssey*, as well as in writing many original poems. But not only was he browsing in the world classics: he traveled and visited the lands of many people. In 1925, he visited Palestine and participated in the opening of the Hebrew University on Mount Scopus, where he worked for a short time in the Kupath Holim Hospital, then returning to Berlin. In 1928, he came to the United States. Here he received the honorary degree of Doctor of Hebrew Literature from the Jewish Institute of Religion. In November, 1928, he went to Cambridge, the home of Longfellow whose poems he translated. While here, he visited the Hebrew Teachers College, where American Jewish youths, students at American universities, studied his Hebrew poems. Everywhere in the New World he was greeted as the poet symbolizing the New Palestine and the renaissance of the Hebrew language.

In 1931, Tchernichovsky returned to Palestine, where he became the physician in charge of schools in Tel Aviv. He was also made an honorary citizen of the city. In 1932, forty years after the publication of his first poem, a special Jubilee Committee published his works in ten volumes, which included most of his original efforts, as well as his translations of some of the world's classics. What a luxuriant harvest these ten volumes represent! What a contribution to world literature! Here one finds poetry in practically all its forms — idylls, epics, sonnets, lyrics and dramas, and prose as well. Poetic creations of various peoples and tongues — ancient and modern — attracted his sensitive soul and he rendered them into Hebrew. Songs of ancient Egypt, Babylon and Greece, as well as the works of Shakespeare, Longfellow, Molière, Goethe, Heine, Pushkin and Alfred de Musset, were among his translations. Heroes of these nations were as stimulating to him as some of the Biblical heroes of his own people.

In 1935, as a result of his translations of the Finnish epic *Kalevala*, Tchernichovsky was invited to Helsinki, where he received the award of the Finnish White Rose. Honors were also bestowed on him by the Academy of Athens for his translations of Homer and Plato.

During his stay in Tel Aviv, Tchernichovsky reached the zenith of his productivity. In addition to the continuous flow of his poetical creations, he completed from 1931 to 1933 a Hebrew medical dictionary begun by Dr. Mazia. It is a book of nearly one thousand pages. For each term is given its Latin, English and Hebrew equivalents. Here again, the poet, physician, philologist and scientist found an outlet. Some of the medical terms

have a poetical tinge to them. Where he could not find an old term hidden somewhere in the ancient literature, he coined a new one. Hebrew, by the touch of this doctor-poet's hand, became rejuvenated, young, vivacious, expressing every mood, every flower and every precious stone, as well as many new inventions. In reading his poetry, one feels the vitality, frivolity and energy of a living tongue and at the same time the wisdom and judgment of old age, vast experience and ripened maturity.

In many of his poems, Tchernichovsky endeavored to revitalize his people and to arouse in them a will for the joy of life. He wanted his readers to respond to the symphonic harmonies of nature and to enjoy its sunshine.

For his stare is Life, and Life and Love are One,
And death's domain is where there is no sun.

Bialik glorified the *Hamathmid* — the diligent student, the guardian of the holy fire, the intellect. Tchernichovsky, on the other hand, stressed the emotional side, bearing out his philosophy, or rather poetical vision of life, according to which the feelings and emotions are superior to the intellect. A sense of beauty is superior to the accumulation of facts, no matter how essential. As he says:

In all the world, three precious crowns there be,
Each crown with its own light for men to see,
Of strength, of Torah, and of beauty are the three.
Our praise to strength!
To Torah's crown, no less,
Of beauty's worth, who shall attempt to guess?*

In another poem, "*Sholosh Amitoth*" ("Three Truths"), he says:

There are three truths in the world — each truth and its particular glory. The truth of the individual — the truth of strength; the truth of the Torah — the truth of the many — the truth of beauty, the universal truth. Truth of beauty is noble and superior to all.

There is a great deal of truth and realism in these verses. Here is a poetic differential diagnosis of a keen and observant physician. Does not the world witness at the present time the curse of intellect without the slightest sense of beauty? Were not evil forces unleashed on the world by a nation that was technically developed and scientifically informed? Are not the foundations of civilization crumbling because a sense of beauty has given way to technical success?

So the doctor turned to beauty wherever it could be found. This prompted him to say enthusiastically to the statue of Apollo, the symbol of youth, love and life:

To thee I come, O long-abandoned God
Of early moons and unremembered days,
To thee whose reign was in a greener world
Among a race of men divine with youth,
Strong generations of the sons of earth.

For this type of poetical utterance, Tchernichovsky was erroneously labeled as the Greek in Hebrew

*Translated by Dr. M. Waxman.

literature. As a matter of fact, it is the Jew in him that speaks in this way — a Jew conscious of his long literary heritage. Was not the poet of the Song of Songs crying for love and life when he said:

Let him kiss me with the kisses of his mouth —
For thy love is better than wine.

In truth, Tchernichovsky is a firm believer in the God of the Bible, for he ends this poem by saying:

I kneel to life, to beauty and to strength,
I kneel to all the passionate desires
Which they, the dead-in-life, the bloodless ones,
The sick, have stifled in the living God,
The God of wonders of the wilderness,
The God of gods, who took Canaan with storm
Before they bound Him in phylacteries.

Tchernichovsky's rare personality and poetry, the vital elements harmoniously fused and mutually influenced each other. He symbolizes by his person the Jew of the Biblical period, by his nature the Jew of the modern poet and by his training the keen and observant physician. He is neither pantheistic in his poetry nor pantheistic in his faith. He is sensitive to beauty everywhere. He would use a Greek theme as a frame to reveal more sharply the ideas of his people. This is clearly revealed in the poem "*Ha-Pesul*" ("The Statue"), dedicated to the students of the Hebrew Gymnasium in Lithuania. He colorfully and artistically describes the pomp and ceremony in a Greek temple at the unveiling of a new statue of the God Zeus. The curtain rises and the entire congregation kneels in awe. Only one person remains standing — the sculptor of this marvelous statue. For at the moment of the unveiling there appears before him the face of the Lord — that is even more sublime, more beautiful and more divine. Does not this poem reveal the great Jew as well as the great poet? When it comes to the suffering of his people, the doctor, as well as the poet and prophet, comes to the front. Tchernichovsky neither weeps nor mourns. There is nothing pusillanimous about his poetry. He is like a great physician who loses his favorite patient and deeply feels the pain and sympathizes with the family, but calmly analyzes the case and goes to his next patient. Having isolated the cause of the illness, Tchernichovsky is encouraged to conquer the malady and wipe it off the earth. Here is where he differs from his predecessor, the immortal Bialik. During the massacre in Russia in 1909, Bialik wrote a poem called "*Be-ir Ha-Haregah*" ("In the City of Slaughter"). Here he appears as a new Jeremiah, with a modern scroll of lamentation. He proclaims to the world the cruelty of man to man. His descriptions are soul piercing and tear at the fibers of the heart. This poetry conveys the wrath and sorrow that only the poet of a martyred people could describe. It is written in a hammered Biblical style, slow moving and weighty rhythm. The poem gives the effect of a memorial hymn played on a gigantic electric organ whose

vibrations rise to pierce the skies and to shake the earth at the same time. Bialik is at times despondent.

Tchernichovsky, the physician, is more comforting. He speaks in the style of Isaiah. He, too, feels the sorrow, the pangs of injustice, but the doctor is calm and not despondent. In 1920, during the slaughter of his innocent brethren in the Ukraine, he wrote a poem called "*Zoth Tchi Nikmatheinu*" ("This Will Be Our Revenge"). "No one listens to the pangs of the widow, no one comforts the infant, but there is revenge in the world." This revenge is not to come by retaliation — he is too sensitive for that. There shall be no retaliation until the image of God is erased from us, as well as the lines of ancient nobility that are on us. It shall not come as long as we bear the yoke of the Ten Commandments. But remember — these acts of murder will poison the very soul and the very fibers of the tormentors. It will breed more cruelty, more immorality and more demoralization. It will penetrate into the heart of the children and their children's children for generations to come. For the cry of blood must be stilled. Here the doctor looks on evil and cruelty as on deadly poisonous bacteria that produce a bacteriophage that eventually destroys the bacteria that produced it. How prophetic is the doctor's prognosis! Nations that permitted evil forces to victimize innocent peoples are now reaping the fruit of the harvest. Here is poetry to be taught to the world, to be included with other rules of medical hygiene for the soul.

Such is briefly the life and work of the doctor and poet, Tchernichovsky. But to appreciate him fully one must read his poems in their entirety and in the original. He belongs to the golden chain of Hebrew poets and physicians. Dr. Tchernichovsky was not a rare phenomenon in the long history of his people. There is a golden tradition of nearly ten centuries of medical Hebrew poets. Each one, more or less, reflected the period of world history in which he lived. As early as the eleventh century, we find the physician in Cordova, Spain — namely, Judah-Ha-Levi (1085-1142). He was a philosopher and a serene and tender poet whose devotional songs in the spirit of the *Psalms* are included in the synagogical liturgy. He too had a longing for Zion that inspired him to compose a number of beloved poems. He too was buried in Palestine in 1142.

During the Golden Age of Hebrew culture in Spain, we find two other Hebrew medical poets: Judah al-Harizi (1170-1230) and Joseph Zabarba (1140-1200). Both were contemporaries of the great Maimonides. All were heirs to a noble tradition of intellectual activity.

In the thirteenth century there lived in Italy the medical Hebrew poet, Immanuel Ha Romi (1265-1330). He reflected the period of his time and was respected by Jews and Gentiles, especially the

literati of the age. He was a friend of Dante and wrote a fine elegy in Italian after the latter's death. In the eighteenth century flourished the poet Ephraim Luzzatto (1729-1792). He died in London. In the nineteenth century there was Judah Lob Katzenelson (born in Tchernigow in 1847; died in Petrograd in 1917). He was a physician and scholar who wrote poems and sonnets, in both Russian and Hebrew, as well as a Hebrew work on talmudic medicine. Finally comes the minor Hebrew poet and physician, Isaac Kaminer (1836-1901).

* * *

Such is the golden tradition of Hebrew medical poets, among whom Dr. Tchernichovsky was the ultramodern. His muse raised him to new heights in poetry.

Tchernichovsky died of leukemia in the Hadassah Hospital in Tel Aviv on October 14, 1943, the first day of Succoth, the holiday of the harvest. His casket was draped in the talith (the prayer shawl) and the Jewish flag. The pallbearers were professors of the Hebrew University and members of the Jewish Agency. The funeral procession was followed by the children of the schools and by soldiers of the Allied forces stationed in Palestine. The poet was buried near his friend, Bialik.

Tchernichovsky is the most modern Hebrew poet who draws his inspirations from the far past —

his roots penetrate deep into the springs that nourished and nurtured the Bible. Like the prophets of old, he also had visions about the future. When his works are rendered by poets into other living tongues, as he rendered the world classics into Hebrew, humanity at large will enjoy its beauty and sunshine, as it does the other sacred writings of his prophets and poets. For Dr. Saul Tchernichovsky had great hopes in the eternal and final victory of man. Mankind may be humiliated at times. "Mobocracy" may unbridle the passions of a populace, and leave the light of civilization a tiny flicker. Yet eventually, our poet believed, the spirit of man will win out.

Laugh, O laugh at all my visions,
For I'm dreaming audibly;
Laugh, for I believe in man still,
For I still believe in thee. . . .
Man shall rise to heights of glory,
Vanity's fetters from him shed,
Till the worker starves no longer,
Spirit freed and hunger fed. . . .
I believe, too, in the future,
Tho' the day's not close at hand;
It will come — then peace and blessing
Will be borne from land to land. . . .
A poet then shall sing a new song.
To beauty exalted then awake;
From my grave, for him, the young one,
They'll pluck flowers, wreaths to make.

483 Beacon Street

MEDICAL PROGRESS

NEW BIOLOGIC CONCEPTS DERIVED FROM RESEARCH ON SULFONAMIDE DRUGS*

BERNARD D. DAVIS, M.D.†

NEW YORK

CHEMOTHERAPY has a long history, progressing from the older treatment of syphilis by mercurial inunctions to the successful use of such agents as arsenicals, bismuth and quinine against syphilis, malaria and other parasitic diseases. No chemotherapeutic agent, however, has affected so many lives so soon after its discovery as have sulfanilamide and the related sulfonamide compounds, which have opened the era of chemotherapy of bacterial diseases. Investigations involving these drugs have not been limited to practical therapeutic problems; they have led to a number of fundamental advances in pharmacology and have had ramifications in related scientific fields. The value and the

limitations of these drugs in overcoming a variety of infectious diseases are widely recognized; this paper will rather be devoted to a review of the broader biologic implications of the knowledge gained in the ten years in which these compounds have been used.

Several attributes of sulfonamide drugs have contributed to the rapid accumulation of knowledge of their pharmacology. These are chemical simplicity and ease of synthesis, which have permitted rapid development of inexpensive manufacture and widespread use; the possibility of synthesis of a wide variety of derivatives of the original sulfanilamide; effectiveness against susceptible organisms without the aid of the body's natural defenses, permitting in vitro study; dissociation as acids; and the possession of a readily diazotized amino group, which permits accurate and simple colorimetric determina-

†Passed assistant surgeon (R), United States Public Health Service.

tion of concentrations of the drugs at therapeutic levels.

DISTRIBUTION OF THE DRUGS IN THE BODY

The absorption, distribution and excretion of these drugs have been studied extensively, since their concentrations are so readily measured. The bacteriostatic action of a given drug is proportional to its concentration in the body rather than to its dosage. It is therefore desirable so to adjust the dosage as to maintain an optimal concentration in the blood, which strikes the proper balance between effectiveness and toxicity. Blood concentrations of 5 to 15 mg. per 100 cc., which are usually sought for the various drugs, are in general maintained by a daily dosage in adults of 4 to 6 gm. There is, however, significant individual variation in the rates of excretion and of acetylation (which renders the drugs nonbacteriostatic). Patients with decreased renal function excrete these drugs more slowly, so that dosage must be watched even more carefully to avoid excessively high concentrations in the body. Smaller, less toxic doses have been recommended for prophylaxis against the recurrence of rheumatic fever,² and for the treatment of superficial infections of the urinary tract.^{3,4}

The frequent measurement of blood sulfonamide concentration has shown that therapeutic levels are obtained quickly only with a large initial dose followed by small maintenance doses. Because of the time lag of several hours before an orally administered sulfonamide is absorbed sufficiently to afford a therapeutic blood level, it is advisable in patients with fulminating infections, such as lobar pneumonia and meningitis, to administer the initial dose intravenously in the form of the sodium salt. This system of variable dosage might well be of value with other drugs, since the lack of chemical methods of measuring concentrations of most drugs has caused physicians to think traditionally in terms of fixed dosage rather than according to the more significant concept of concentration in the body. There are wide variations in individual tolerance to certain drugs, such as aspirin and colchicine; methods of measuring blood levels might contribute materially to a rational employment of these substances. This approach has recently been successfully applied to the salicylate treatment of rheumatic fever.⁵

The levels of sulfanilamide found in the cerebrospinal fluid are usually almost as high as those present in the blood, whereas the levels of sulfathiazole are only approximately 25 per cent of the blood levels; the ratios of blood to cerebrospinal fluid for sulfapyridine and sulfadiazine are intermediate. At first this was explained by a supposed poor diffusibility of sulfathiazole through the blood-brain barrier, leading to the conclusion that sulfathiazole, although an excellent drug in the treatment of systemic infections, is a poor choice in the treatment of meningitis. This explanation and

clusion was invalidated by the discovery that the sulfonamides are bound in varying degrees to plasma proteins, particularly to albumin.^{6,7} Only .20 per cent of sulfanilamide but 75 per cent of sulfathiazole in plasma is bound. The type of binding noted for sulfonamides is a rapidly reversible equilibrium between protein, bound drug and unbound drug. Since only the unbound drug can permeate into the cerebrospinal fluid, it follows that there is no lack of diffusibility on the part of sulfathiazole. Further, since it is highly probable that only the unbound drug is bacteriostatic,⁸ the 1.2 mg. per 100 cc. of sulfathiazole in cerebrospinal fluid, which is essentially protein-free, would be expected to be as effective as the 5 mg. in the corresponding plasma, of which only 1.2 mg. is unbound. This theoretical analysis is supported by numerous clinical observations of the efficacy of the highly bound sulfathiazole and sulfadiazine in the treatment of meningitis. There is now no justification in treating any case of meningitis with the relatively ineffective sulfanilamide. It may also be pointed out that binding to nondiffusible constituents is a mechanism that must be borne in mind in interpreting the distribution of any drugs or other permeable substances between intracellular and extracellular fluids or between two extracellular fluids such as cerebrospinal fluid and plasma.

MODE OF ACTION

It was early observed that the sulfonamides exert little bacteriostatic effect in the presence of pus, meat extract, yeast extract and other biologic mixtures — indeed, they are quite ineffective in the local or systemic treatment of walled-off purulent infections unless the pus can be drained. Woods⁹ tested the effect of various chemical reactions on the inhibiting power of yeast juice, and concluded that the inhibiting factor behaves exactly like *p*-aminobenzoic acid. This pure compound was in turn found to be a powerful inhibitor, interfering with the action of sulfanilamide when present in only one five-thousandth of the concentration of the drug. A practical result of this discovery has been the addition of *p*-aminobenzoic acid to the medium used for cultures in cases receiving a sulfonamide, to eliminate the possibility that the drug present may mask the presence of bacteria.⁹ A much more important outcome is the theoretical concept of competitive inhibition between sulfonamides and a metabolite, *p*-aminobenzoic acid, essential for the multiplication of the organism.⁸ Proof of this concept depends on evidence that *p*-aminobenzoic acid is an essential growth factor for sulfonamide-susceptible bacteria. Diligent search has disclosed very few organisms — and these nonpathogenic — in which *p*-aminobenzoic acid appears to be a growth factor^{10,11}; for the rest it is necessary to assume that the organism synthesizes *p*-aminobenzoic acid to meet its normal

ments, but not enough to compete with bacteriostatic concentrations of sulfonamide drugs.

It is assumed in analogy to the participation of such vitamins as thiamine and niacin in oxidation-reduction enzyme systems that *p*-aminobenzoic acid is a vital link in some enzymatic mechanism. The sulfonamides on this assumption compete by possessing a chemical configuration that permits them to occupy a position in the enzyme that is ordinarily held by *p*-aminobenzoic acid, but lack the complete configuration necessary for the function of the latter. That *p*-aminobenzoic acid and the sulfonamides may be expected to be attracted to a similar position on an enzyme molecule follows from the extremely similar configurations of their structural formulas. Although the nature of the enzyme concerned is as yet completely unknown, the concept that sulfonamides act by competitive inhibition of an enzyme reaction is widely accepted.*

The bacteriostatic action of sulfonamides does not necessarily occur immediately, for it has been shown with *Escherichia coli* that multiplication takes place for about six cell divisions before it ceases in the presence of adequate concentrations of sulfonamides.¹⁴ The implications of this fact for the mode of action of the drug are not clear; it may possibly be related to the available stores of *p*-aminobenzoic acid. From a practical point of view, this emphasizes the importance of early treatment and may be one reason why overwhelming cases of meningitis or pneumonia are fatal in spite of treatment by a sulfonamide drug to which the organism is susceptible.

Considerable understanding has been gained by studying the bacteriostatic efficacy of a series of compounds derived from sulfanilamide by substitutions in the amide radical. Although the precise values reported for the drugs vary with the organism, medium and particular end point chosen, in vitro studies indicate that, in contrast to the early impressions, there is no specificity of any particular drug for a given organism.¹⁵ In the earlier studies on the physical chemistry of these drugs,^{16, 17} it appeared that the bacteriostatic power could be correlated with the extent to which the drug was ionized as an anion at the hydrogen-ion concentration of body fluids or ordinary culture media (pH 7.4). The degree of ionization is conveniently represented by the pK, which is the pH at which the drug is 50 per cent ionized. Thus, at pH 7.4 sulfathiazole (pK 7.1¹⁸) is largely ionized whereas sulfanilamide (pK 10) is ionized to the extent of only a fraction of 1 per cent and hence must be present in much greater concentration in order to be effective. This explains the excessive disproportion in the concentrations of sulfanilamide and *p*-amino-

benzoic acid competing with each other, since the latter is essentially completely ionized at pH 7. With recalculation in terms of concentration anions, *p*-aminobenzoic acid and various sulfonamides compete with each other in similar concentrations.¹⁷

Further work with new drugs showed this scheme to be an oversimplification, for when drugs were synthesized with pK values even lower than that of sulfathiazole, and consequently were even more completely ionized at pH 7.4 than is sulfathiazole, they were found to be less bacteriostatic.¹⁸ This can be explained by assuming a dependence of bacteriostatic potency on certain physicochemical functions (acidity of the anion¹⁹ or negativity of the sulfonamide group¹⁸) that vary with the pK, having a maximum value at about pK 6.8. These theories lead to the prediction that it will be impossible to synthesize a member of this series, working by the same mechanism, that will be more bacteriostatic than are sulfathiazole, sulfadiazine, sulfamerazine and certain other sulfonamides now in widespread clinical use, which have pK's at or close to the maximum. Efforts to improve on the present compounds must, then, be aimed at a reduction in toxicity, or at a change of structure so radical as to introduce a new mode of action.

The binding of sulfonamides to plasma proteins, which was discussed in connection with the problem of distribution in the body, was found to parallel the in vitro bacteriostatic potency of a series of sulfonamide compounds, the drugs with the greatest binding tendency being in general the most bacteriostatic.²⁰ This correlation suggests that the drugs in their assumed action by competition with *p*-aminobenzoic acid are bound to the hypothetical enzyme by the same forces that bind them to other proteins. Sulfamerazine and sulfamethazine, which have recently been found to be potent drugs, are all highly bound.²¹

RESISTANT STRAINS OF ORGANISMS

The bacteriostatic action of sulfonamides cannot involve an enzyme system that is universally present and susceptible in bacteria, since these drugs are effective against only a limited number of gram-positive and gram-negative organisms. Furthermore, certain patients have been found to be infected by drug-resistant strains of a number of ordinarily susceptible species of organism, where others have strains that become resistant during the course of prolonged exposure to moderate concentrations of the drugs in vitro or in vivo.²² The study of metabolic differences between resistant and susceptible strains appears to be one of the most attractive methods of probing further into the mode of action of the drugs. Certain sulfonamide-resistant strains of *Staphylococcus aureus* have been reported to synthesize *p*-aminobenzoic acid, which can be detected in the filtrate from the organisms.

*It has been noted that sulfanilamide inhibits the enzyme carbonic anhydrase,^{12, 13} which is responsible for the rapid conversion of carbonic acid or bicarbonate to free carbon dioxide in the body. This property accounts for the moderately depressed plasma carbon dioxide combining power sometimes noted in patients receiving sulfanilamide, but since the property is not shared by the other drugs in the series, it cannot be concerned in their bacteriostatic action.

but since the method of detecting this acid was biologic rather than chemical, it is not certain that the drug-inhibiting substance elaborated by the organisms was actually *p*-aminobenzoic acid.

In the study of earlier chemotherapeutic agents, it has been difficult to obtain direct evidence of the relation between resistance to treatment and variations in the host and in the infectious agent. With syphilis, indirect evidence indicates that in at least some cases resistance to treatment depends on factors in the host rather than on variations in the strain of the organism.²¹ The effectiveness in vitro of sulfonamides has made it possible in many cases of gonorrhea and other diseases to place the responsibility for failure of therapy directly on the organism. With the gonococcus, a simple method has recently been developed for testing in vitro the response to sulfathiazole of each patient's strain of organism.²² This permits accurate prognosis of the results to be expected from sulfonamide therapy and minimizes the time wasted before recognizing the desirability of other forms of therapy — for example, fever and penicillin — in sulfonamide-resistant cases. As the variety of available chemotherapeutic agents grows larger this principle will undoubtedly find ever-increasing application, especially with serious diseases where the saving of life may depend on early use of an effective drug.

TOXICITY

Even the best drugs now available give rise to toxic reactions, reported in as high as 10 to 15 per cent of some series, which are occasionally fatal. A large proportion of the toxic reactions of these drugs (except for the relatively soluble sulfanilamide) are due to the unusually large doses necessary and the low solubility of their acetyl derivatives. These properties, together with the high renal clearance of these compounds,^{26, 27} frequently lead to concentrations in the urine in excess of their solubility, with resultant crystallization in the urine. Sufficient crystallization occurs in the tubules or ureters, renal damage results, but it is not clear whether all the toxic effects of sulfonamides on the kidneys arise from such precipitation. With drugs of which the degree of ionization varies significantly in the pH range of the urine — for example, acetyl sulfadiazine — the solubility can be markedly increased by rendering the urine alkaline. This type of toxic reaction can therefore be circumvented with certain drugs by administration of alkali.^{28, 29} Urca has also been shown experimentally to inhibit renal precipitation of the drugs.³⁰

The other toxic reactions are much less well understood and consist largely of primary toxic effects — for example, nausea, vomiting, headache and mental confusion — and a group of reactions that are usually delayed — hemolytic anemia, agranulocytosis, jaundice and drug fever, with or without a rash. Longcope³¹ has recently stressed the similarity

of the latter group to serum sickness, pointing out that although clinically these reactions of sulfonamides and other chemical drugs have many characteristics of sensitization phenomena, direct proof by demonstration of antibodies has not been obtained, and most workers have failed to demonstrate skin reactions to the drugs with any regularity. The unpredictability and persistence of these hypersensitive reactions present a contraindication to the use of these drugs in treating relatively trivial infections or in prophylaxis, and therefore limit their utility.

METABOLIC STUDIES

Although it has already been established that certain drugs act by inhibiting enzymatic activity,³² — for example, physostigmine inhibits choline esterase, — the present concept of the mode of action of sulfonamides by competitive inhibition of an enzyme provides a further thought-provoking link between drugs, vitamins and enzymes. It has already led to two important developments outside the field of chemotherapy. In the first place, *p*-aminobenzoic acid has been found to be an essential dietary factor in rats and chicks,^{33, 34} although evidence has been presented that this action may depend on stimulation of certain gastrointestinal micro-organisms to synthesize essential factors.³⁵ In the second place, competitive inhibition has been shown between other vitamins and structurally similar compounds, which behave as antivitamins. Thus the pyridine derivative of thiamine interferes with the growth of bacteria that require thiamine.³⁶ Similarly, nicotinamide and the co-enzyme derived from it have been observed to antagonize the effect of various sulfonamides on the growth of *Staph. aureus*,^{37, 38} whereas sulfapyridine and sulfathiazole (but not certain other sulfonamides) inhibit the stimulation of the respiration of the dysentery bacillus by nicotinamide or the co-enzyme.³⁹ The similarity of chemical configuration between nicotinic acid and sulfapyridine may not be an important factor in this antagonism, since the other sulfonamides that exhibit the reaction do not have the pyridine nucleus of these two compounds.

The metabolic effects of the sulfonamide drugs are not confined to bacteria. Evidence of the importance of antivitamins as well as vitamins in animal nutrition has been provided by the observation that sulfapyridine inhibits the curative action of nicotinic acid in dogs suffering from a deficiency of this vitamin.^{40, 41}

Sulfaguanidine and sulfasuxidine (succinyl sulfathiazole) are sulfonamide drugs with properties of solubility and absorption that permit high intestinal concentrations along with low concentrations in the body fluids. These drugs have been used in the treatment of certain types of enteric infection and in preoperative prophylaxis of peritoneal infection following gastrointestinal surgery. ¹

this practical utility, the drugs have provided an explanation for apparent differences in the vitamin requirements of various animal species. Whereas the concept of synthesis of vitamins by bacterial flora was first developed in relation to vitamin K, the suppression of such synthesis by these sulfonamide intestinal antiseptics has permitted the demonstration that biotin⁴² and folic acid^{43, 44} are essential for complete nutrition of the rat's tissues as well as of bacterial and animal species in which they have earlier been proved to be essential. The elimination of intestinal bacterial synthesis may be expected to provide further solutions of problems in vitamin research. The production of leukopenia and anemia in rats by these drugs permits a new experimental approach to the problem of blood dyscrasias.⁴⁴

An entirely new field of chemotherapy, not involving infections, has arisen from the observation that rats receiving huge doses of sulfonamides developed an enlargement of the thyroid gland shown to be due to interference with the response of the gland to the thyrotropic hormone of the anterior pituitary glands.^{45, 46} Further investigation of this phenomenon led to the development of other unrelated compounds, thiourea and thiouracil, that have proved useful in the treatment of hyperthyroidism, and that may in the future replace much of the surgical treatment of this disease.⁴⁷

* * *

Besides their great practical utility, the sulfonamide drugs have provided valuable fundamental advances in pharmacology and related fields, which may serve as a pattern for the study of the reactions of other drugs with the host and with the infecting agent. Their distribution in the body is primarily dependent on their degree of binding to plasma albumin, which in turn parallels their bacteriostatic power in its dependence on certain physicochemical functions of the acid-base dissociation constants of various members of the series. The antagonism between sulfonamides and a closely related chemical, *p*-aminobenzoic acid, has led to a theory of the mode of action of these drugs by competitive inhibition of a postulated bacterial enzyme. Para-aminobenzoic acid has subsequently been recognized as a vitamin in the nutrition of certain vertebrates, whereas the concept of competitive inhibition has led to the discovery of other antivitamin. Intestinal antiseptics by sulfonamides has made possible the discovery of new food factors essential in mammalian metabolism. Investigation of a toxic effect of massive sulfonamide therapy in animals has led to the development of other compounds that may significantly modify the treatment of hyperthyroidism.

The broad utility of sulfonamides has developed an unprecedented interest in the field of chemotherapy. It may be partly by virtue of this stimulation that penicillin, which lay relatively unrecognized for ten years following its discovery by Fleming

in 1929, has finally been found to surpass the sulfonamides in therapeutic effectiveness and freedom from toxicity. The development of other chemotherapeutic agents of microbial and synthetic origin offers future possibilities that may ultimately extend well beyond the range of infectious diseases.

CASE 30241

PRESENTATION OF CASE

A fifty-seven-year-old housewife entered the hospital because of pain in both sides of the abdomen.

The patient had been in apparent good health until two years before entry, when she experienced a knife-like pain in both lower quadrants of the abdomen. The pain caused the patient to double up and remained fairly severe for seven days. It was more marked on the left than on the right, was spasmodically crampy and did not radiate. Within six hours of the onset of illness, she developed nausea and vomited greenish material, without any gross blood, coffee-grounds or fecal material or recognizable food. The vomiting was followed by "watery diarrhea" in which no blood or mucus was apparent. She had no chills or fever. She was seen by her physician, who prescribed pills and bed rest. The symptoms disappeared in about two weeks, and she felt "fine" during the ensuing seventeen months. Seven months before entry she had recurrence of the pain in the lower abdomen. This time, however, the pain was dull, not crampy, and of much less intensity according to one story, but crampy and knife-like by another. It involved both lower quadrants, but was a little more pronounced on the left than on the right, and radiated to the vagina and to both flanks. She vomited greenish material and had diarrhea productive of bright red blood and mucus. This apparently lasted for several hours, but these attacks recurred on the average of once a month, continuing one or two days but without blood in the stools. Between the attacks she felt weak and had a poor appetite. During the

last month before entry, the pain became almost constant and there were bouts of diarrhea, the last episode occurring two days before admission. She had lost 30 pounds in six months. There had been no disturbance of urination.

She had had an appendectomy and a bilateral oophorectomy twenty-four years before admission.

Physical examination showed a well-developed, obese woman in no discomfort. The heart and lungs were normal. There were a sense of resistance and an indefinite mass in the suprapubic region. Rectal and pelvic examinations were negative.

The blood pressure was 130 systolic, 90 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood showed a red-cell count of 2,850,000, with 65 per cent hemoglobin. The white-cell count was 6900, with 74 per cent neutrophils. The urine was negative. One stool examination was guaiac negative. The nonprotein nitrogen was 25 mg. per 100 cc., and the protein 6.1 gm.; the blood chloride was 109 milliequiv. per liter. A blood Hinton test was negative. Proctoscopic examination was unsatisfactory in that the proctoscope could not be passed into the sigmoid, but so far as could be seen the mucosa was normal. A barium enema showed a pressure defect on the medial aspect of the cecum, which was thought to be due to an extrinsic mass. The terminal ileum could not be filled. The cecum was quite spastic, and could not be filled satisfactorily. A gastrointestinal series was unsatisfactory because of technical difficulties. Fluoroscopically, the esophagus, stomach and duodenum were negative. The motor meal passed easily to the lower ileum and proximal colon. Several loops of the ileum were slightly dilated. The terminal 10 cm. appeared definitely narrow, and the mucosal pattern was not visible (Fig. 1). There was some swelling of the ileocecal valve, and a definite constant deformity of the cecum. A repeat barium enema showed ready filling of the colon. The cecum was spastic, but no constant defect or evidence of pressure on the cecum was seen. No barium entered the terminal ileum. An intravenous pyelogram was negative.

Following admission the patient had vomiting and pain in the lower abdomen for a day or two, but these disappeared. On the eleventh hospital day, a sigmoidoscopy was introduced through the Miller, which showed a lesion in the terminal

and cecum. No definite shelf could be seen. The mucosal pattern was partially preserved, and there was some swelling of the ileocecal valve. She was given several transfusions, and on the fifteenth hospital day an abdominal exploration was performed.

DIFFERENTIAL DIAGNOSIS

DR. HORACE K. SOWLES: Apparently from the story the cramps two years before entry were of a mechanical nature. The recurrent pain in the lower

shown a lesion in the terminal ileum. This could have accounted for her type of symptoms, because she might have had temporary obstruction or partial intussusception at the ileocecal valve, which caused the attacks of pain and vomiting and also, on one occasion, blood in the stools.

The lesions of the terminal ileum are not many. There was apparently no evidence in the x-ray films to suggest regional ileitis, tuberculosis or ulcerative colitis. [Perhaps it was a tumor of the terminal

FIGURE 1. Spot Film of the Ileocecal Region Showing the Lesion at the Terminal Ileum.

abdomen was of the spasmodic type, and there was no fever. Seven months before entry she had a recurrence of these attacks.

The laboratory findings on entry were normal, with the exception of the red-cell count and hemoglobin, which showed a definite anemia. The physical examination was noncontributory. The barium enema, however, revealed a definite lesion. On one occasion the x-ray examination showed something at the cecum that may have been extrinsic, although that was not confirmed on the second examination. The second observation seems to have

ileum, such as a sarcoma or carcinoma. They are rare, but they do occur. A small tumor in the terminal ileum can easily cause intussusception, which would explain the pain but not the severe secondary anemia. One does not usually see a marked anemia like this with lesions of the terminal ileum. It does, however, occur with carcinoma of the cecum; but the x-ray report says that the cecum was normal.

The patient had a secondary anemia and a marked weight loss, so my first guess is malignant disease of the ileocecal valve, and my second choice, regional ileitis, which does not explain the loss of

weight and the anemia so well as carcinoma. Tuberculosis is unlikely. I do not believe that it could have been anything in the pelvis.

In passing, the commonest extrinsic mass around the cecum is an appendiceal abscess, which is not possible in this case because of the previous appendectomy. Furthermore, there is nothing in the history that suggests it.

DR. BENJAMIN CASTLEMAN: Would you like to look at the x-ray films?

DR. SOWLES: Yes; perhaps the roentgenologist can tell me something that will change my opinion.

ANATOMICAL DIAGNOSIS

Malignant carcinoid of ileum, with metastases to regional lymph nodes.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The clinician in charge of the patient leaned, I believe, toward regional ileitis rather than tumor. At operation the surgeon felt a mass in the region of the terminal ileum and resected the terminal ileum, the cecum and part of the ascending colon. The terminal ileum was markedly

FIGURE 2. Drawing Showing the Lesion in the Terminal Ileum

The insert represents a cross section of the tumor, with neoplastic tissue above and below the muscularis.

DR. MILFORD SCHULZ: These films demonstrate a lesion in the terminal ileum. The persistent irregularity of the cecum looks more like spasm than infiltration. The mucosal pattern in the terminal ileum is somewhat altered.

DR. SOWLES: If the lesion was a carcinoma, it probably arose in the ileocecal valve, the thickening of the terminal ileum being due to edema. Such lesions are not, as a rule, primary in the ileum.

CLINICAL DIAGNOSIS

Regional ileitis.

DR. SOWLES'S DIAGNOSIS

Tumor at ileocecal valve, probably carcinoma.

dilated. Just proximal to the ileocecal valve, there was a 3-cm mound-like tan lesion, composed of nodules that were covered with a thin layer of mucosa (Fig 2). These nodules extended on to the edematous tip of the valve, which protruded into the cecum for about 3 cm. On cross section some of the nodules extended through the muscularis into the serosa.

At this point, would you like to commit yourself further, Dr. Sowles?

DR. SOWLES: My idea that the pain was due to partial intussusception is proved by the findings. Of course, the commonest cause of intussusception, except in small children, is a tumor of the bowel wall, which is a nucleus for the intussusception. I suppose that it could have been a . . . but

I should think that, because of the marked anemia, she must have had malignant disease of the carcinomatous type.

DR. CASTLEMAN: The tumor involved the entire mucosa, submucosa and muscularis, extended into the serosa and was also present in the adjacent lymph nodes (Fig. 3). All the tumor cells were uniform in size, perfectly round and grouped in masses. The appearance is characteristic of a carcinoid or argentaffinoma—a tumor that arises from the argentaffin cells of the small intestine. These tumors are usually benign, but in perhaps

FIGURE 3. Photomicrograph of a Metastatic Lesion in a Regional Lymph Node.

Note the characteristic carcinoid cells.

less than half the cases they metastasize to the regional nodes, where the cells may remain for years without going any farther. They are not uncommon incidental autopsy findings if they are hunted for. The tumors invade the mucosa, but ulceration rarely occurs.

The involvement of the lymphatics in the wall of the bowel and of the regional nodes makes this case a malignant carcinoid. In addition, at operation the surgeon felt a mass in the liver, so it had apparently gone farther than the regional nodes. We have had in the past, I believe, two or three other cases in which the tumor had metastasized farther than the regional lymph nodes, but it is extremely rare. I should think that, even though

the patient had a mass in the liver, the prognosis is good for a number of years. These tumors grow extremely slowly. I recall a patient on whom the late Dr. Daniel F. Jones operated for small-bowel obstruction, finding a tumor with a large adherent mesenteric mass of metastases. He resected the small bowel, but left the metastases. This was in 1913, before these tumors were separated from carcinomas, although Dr. J. Homer Wright in his surgical report said, "The arrangement and appearance of these cells suggest the type of cancer that is found in the appendix." The man died twenty years later at this hospital following a prostatic operation, and at autopsy there were the same masses of nodes that Dr. Jones had left in. Some had become calcified, but microscopically they showed carcinoid.

CASE 30242

PRESENTATION OF CASE

A sixty-six-year-old man entered the hospital because of "bladder trouble."

For many years the patient had a great deal of "bladder trouble." About fifteen years before entry he had a left nephrectomy for "pus in the kidney." Following this, his condition improved for a year or two, but then he developed frequency and urgency of urination, with pain and burning. He had aches and pains in the region of the right kidney. About four or five weeks before entry, following a prostatic massage by his physician, he experienced increasing burning, frequency and urgency. There was no change in the urinary stream. The urine was cloudy. He had had no chills or fever.

He had had a chronic cough productive of yellowish-white, thick sputum for many years. For four years before entry he had had shortness of breath on exertion and orthopnea. About seven months before entry he developed ankle edema and "fluid in the lungs." He was put on $1\frac{1}{2}$ gr. of digitalis daily, but the time was reduced to every other day because of an episode of nausea and vomiting. Dyspnea on exertion continued. About two weeks before admission he was seen in the Emergency Ward because of urinary difficulty.

Examination showed considerable difficulty on breathing, with prolonged expiration. The chest was emphysematous. The lungs were full of coarse wheezes. There was tenderness over the bladder. Rectal examination revealed a small nontender prostate, but the base of the bladder and the surrounding areas were exquisitely tender.

The blood pressure was 115 systolic, 70 diastolic. The temperature was 98°F., the pulse 80, and the respirations 30.

The urine was cloudy, with a pH of 6, a specific gravity of 1.010, and a ++ test for albumin. The

sediment contained numerous white cells and occasional red cells.

The patient was given hot sitz baths, demerol and sandalwood oil. He was also given 10 drops of a saturated solution of potassium iodide three times a day, $3\frac{3}{4}$ gr. of aminophyllin four times a day by mouth and $1\frac{1}{2}$ gr. of digitalis daily. Following this, the dyspnea and orthopnea disappeared. Although there was some relief of urinary trouble, he was still in considerable discomfort because of pain and burning on urination. Two days before admission to the ward he developed "an asymptomatic morbilliform and acneiform rash over the entire body and a conjunctivitis." He had had no chills or fever.

Examination on admission showed a patient who looked sick and complained of pain in the bladder. He was not dyspneic. There was a diffuse morbilliform and acneiform rash over the face, neck, arms and trunk. Moderate conjunctivitis and a yellow discharge were seen in both eyes. The pupils were small and fixed. Some moist rales and intermittent rhonchi were heard in both bases. The chest was emphysematous. The heart was of normal size. The sounds were distant, and a slight systolic murmur was heard over the precordium. A tender mass, measuring 6 by 7 cm., was palpated in the right flank that seemed to have some connection with the liver and that was finally believed to be a Riedel lobe of the liver. The edge of the liver extended 4 cm. below the costal margin and was tender. There was exquisite tenderness over the prostate and bladder.

The blood pressure was 90 systolic, 40 diastolic. The temperature was $102^{\circ}\text{F}.$, the pulse 120, and the respirations 30.

Examination of the blood showed a red-cell count of 5,700,000, with 18 gm. of hemoglobin. The white-cell count was 15,300, with 72 per cent neutrophils. The urine contained many white cells and gave a +++ test for albumin.

Potassium iodide was stopped. He was given 2 cc. of Cedilamid intravenously, followed by 100 cc. of aminophyllin intravenously. The skin rash disappeared in twenty-four hours, but the patient's general condition seemed worse. The lungs showed many moist rales. He developed fecal and urinary incontinence and became unresponsive. The non-protein nitrogen was 60 mg. per 100 cc. He was given intravenous fluids and 1.25 gm. of sulfadiazine intravenously. A Foley catheter was placed in situ. He became anuric, developed marked abdominal distention and Kussmaul breathing, and died on the third hospital day.

DIFFERENTIAL DIAGNOSIS

DR FLETCHER H. COLBY: Here is a patient with a long story of bladder trouble. First of all, I think it is reasonable to exclude malignant disease because of the long duration of the symptoms. The outstanding complaint was bladder irritability. In

addition to this the patient had some sort of chronic disease, with emphysema or possibly bronchiectasis, which perhaps put a severe load on his heart, so that he had a certain amount of cardiac difficulty. In all probability that is aside from the main issue—the bladder trouble.

The patient went to the Emergency Ward two weeks before he entered the hospital, complaining of his bladder. When he entered the hospital his chief difficulty concerned the bladder. What are the things that may give long-continued bladder irritability? First of all are the local conditions, infection, residual urine from some obstruction to the free flow of the urine and complete emptying of the bladder, such as stricture or enlarged prostate. These seem to have been eliminated because there had been no change in his ability to void. A vesical calculus may cause irritability and infection. Diverticulum of the bladder with infection may also cause considerable irritability of the bladder. This man, however, had had sufficient local symptoms, with tenderness on pressure over the bladder, to suggest even a pericystitis, involvement of the perivesical tissues, in addition to possible local lesions in the bladder, causing marked, continued, chronic irritability.

There is also the upper urinary tract to be considered, and it is reasonable to look there seriously for the source of the trouble. It is quite obvious that infection of some sort played a major role in this patient's illness. We have no x-ray films, which would be helpful, but we have to get along with the information given to us. He had had a nephrectomy years ago, and at the time of entry probably had involvement of the remaining kidney. The 6-by-7-cm. mass felt in the right upper quadrant was possibly the right kidney rather than the right lobe of the liver.

The conditions that may involve both kidneys are not many. In the first place there are the various congenital abnormalities that result in inadequate drainage of the kidney, such as aberrant vessels and kinks and so forth in the ureters, with hydronephrosis. The kidney that had been removed was said to be a "pus kidney." He might have had the left kidney taken out for a calculus pyonephrosis, and on entry he might have had stones and infection on the other side. Pyelonephritis does not sound reasonable. Any of these conditions may cause long-standing bladder irritability, and almost any one of them can be associated with perirenal infection, which may not be evident on examination. The most obvious lesion, however, to account for long-continued bladder irritability, the involvement of one kidney, with removal, and finally the involvement of the other kidney, is renal tuberculosis. Renal tuberculosis may stay dormant in one kidney for many years. I saw a patient at the Lakes for a villi natorium who, after having had tuberculosis, was

I should think that, because of the marked anemia, she must have had malignant disease of the carcinomatous type.

DR. CASTLEMAN: The tumor involved the entire mucosa, submucosa and muscularis, extended into the serosa and was also present in the adjacent lymph nodes (Fig. 3). All the tumor cells were uniform in size, perfectly round and grouped in masses. The appearance is characteristic of a carcinoid or argentaffinoma—a tumor that arises from the argentaffin cells of the small intestine. These tumors are usually benign, but in perhaps

that the disease simulated heart failure, with shortness of breath; in fact, he had been treated for heart failure, having received digitalis and bed rest, but the dyspnea and orthopnea increased. Probably at the final entry he did have heart failure. He did not respond to aminophyllin or digitalis, and potassium iodide caused apparent toxic irritation. That sort of picture can simulate heart failure. It might be labeled a pulmonocardiac picture. The patient had emphysema, and yet all the evidence is against heart disease, because the heart was normal in size; the blood pressure was normal (115 systolic, 70 diastolic) before he went into collapse. The red-cell count was 5,700,000 and the hemoglobin 18 gm., which was a compensatory mechanism for the red cells in the lung circuit to make up for the emphysema. This was not a true polycythemia.

Coming back to the tender mass, I think it was a hypertrophied kidney diseased with tuberculosis.

DR. COLBY: Dr. Butler has just whispered an important differential factor. Pyogenic infection of the upper urinary tract or of the bladder itself, such as an infected diverticulum, usually does not cause such protracted and distressing bladder symptoms and such tenderness as does tuberculosis.

DR. ALLAN M. BUTLER: The bladder irritation in the presence of long-continued renal infection is the thing that places the emphasis on this being tuberculosis.

DR. JOSEPH C. AUB: I saw this man in the Emergency Ward, and I thought that the mass was a big liver. Secondly, the severe pain was in the prostate and around it rather than in the bladder, and I assumed that he had prostatic abscess, which might have ruptured. He had an infection and was in uremia. I thought that he had pyelonephritis from

the patient had a mass in the liver, the prognosis is good for a number of years. These tumors grow extremely slowly. I recall a patient on whom the late Dr. Daniel F. Jones operated for small-bowel obstruction, finding a tumor with a large adherent mesenteric mass of metastases. He resected the small bowel, but left the metastases. Homer Wright in his surgical report said, "The arrangement and appearance of these cells suggest the type of cancer that is found in the appendix." The man died twenty years later at this hospital following a prostatic operation, and at autopsy there were the same masses of nodes that Dr. Jones had left in. Some have become calcified, but microscopically they showed carcinoid.

CASE 30242

PRESENTATION OF CASE

Cystitis, acute and chronic. the hospital.
Pulmonary tuberculosis, healed, apical.
Pulmonary emphysema.
Bronchiectasis, slight.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The remaining kidney was not particularly large. The upper pole was sclerotic; the lower pole was smooth and somewhat enlarged and, on section, proved to have several reddish-yellow caseous areas. It was suspicious of tuberculosis, but we were not sure at the time of autopsy. The prostate had several small greenish-black abscesses without gross evidence of caseation, such as was present in the kidney. Microscopic sections, however, showed tuberculosis in both the prostate and the kidney. Sections from the bladder, which in the gross was markedly injected and trabeculated, showed no evidence of tuberculosis. The lungs showed healed tuberculosis at the apices, without any evidence of activity. There was a fair amount of emphysema, and in one lower lobe some bronchiectasis.

DR. CHAPMAN: How much bronchiectasis?

DR. CASTLEMAN: Very slight. There was some edema and congestion of the lungs, but no evidence of pneumonia.

DR. AUB: How about the liver?

DR. CASTLEMAN: It was enlarged, and showed marked fatty change. The big mass that was felt was undoubtedly the liver and not the kidney.

DR. JAMES M. NEIL: What did the heart show?

DR. CASTLEMAN: It was normal.

DR. CHAPMAN: You think that the patient died primarily of uremia?

DR. CASTLEMAN: Probably.

"FOOD FIGHTS FOR FREEDOM"

"Food," according to an alliterative slogan currently popularized by our federal nutritionists, "fights for freedom." We are reminded of the similar cliché of twenty-six years ago, "Food will win the war." The new slogan, as compared with the old, does not represent any particularly original idea, but neither does the fundamental principle on which it is based; when the producers of food leave their plows in the furrows and take up their muskets, food becomes a peculiarly precious commodity. That which is almost taken for granted by a large proportion of the population in a still fertile country in times of peace becomes another weapon with which to fight when the country goes to war.

This sudden relative scarcity of life's indispensable fuel brings into an embarrassing limelight certain interesting jugglings with the nation's food supply that are too easily overlooked in normal times when everyone, like the king in Milne's whimsical verse, had a little bit of butter for his bread. Many of our readers will no doubt recall the chapter and verse:

The Dairymaid
She curtsied,
And went and told
The Alderney:
"Don't forget the butter for
The Royal slice of bread."
The Alderney
Said sleepily:
"You'd better tell
His Majesty
That many people nowadays
Like marmalade
Instead."

Times, however, can change. Many people nowadays are being reminded by new governmental agencies, different from those that had helped to suppress it, that oleomargarine fortified with vitamin A is a food the equal in every respect, except perhaps for certain esthetic values, of natural (if sometimes artificially colored) dairy butter. Oleomargarine, moreover, if accepted on the basis of its cost of production, should sell for half the price of butter; an ideal food for the low-income groups in normal times — satisfactory for anyone in difficult times.

Here enters pressure politics, one of the black spots of our democratic system, for in practically every state of the Union where margarine competed seriously with the sale of butter, as well as in the Congress of the United States, laws have been enacted to nullify the economic laws of such free competition. Thus, the Bureau of Internal Revenue is authorized to levy an excise tax on every merchant selling the product, and every state has added one or another type of restrictive legislation, such as taxes ranging from 5 to 15 cents a pound, license fees for manufacturers and vendors and, in some instances, special licenses for restaurants and hotels serving margarine to their patrons.

It was only recently, indeed, that the embattled farmers of Wisconsin rose in their wrath against a scientific investigator in their tax-supported uni-

versity who had dared to make public his findings in favor of margarine as a food substance! Thus does an entrenched interest show that sometimes food can fight against freedom.

ARTHROPOD CONTROL

ARTHROPODS such as bedbugs, ticks, mosquitoes and house, stable and deer flies are well known as pests by civilians in this country, and the role played by certain species of arthropods, such as ticks, mites and biting insects, in the transmission of disease is well appreciated by the medical profession. Previous to the present war, the development of insecticides and newer methods of controlling arthropod vectors of disease was being investigated on a smaller scale than was deserved by the immensity and importance of the problem for the protection and betterment of the public health. The present war, with its widespread outposts and fighting throughout tropical and subtropical areas, brought to the fore the urgent need for better and more effective methods of arthropod control, if major and possible disastrous epidemics of certain parasitic, rickettsial, bacterial and virus diseases were to be prevented.

The challenge of the emergency was accepted by the combined intelligence and efforts of medical officers, entomologists, chemists and sanitary engineers. The foresight of this method of attack is now beginning to show successful results. Obviously much of the experimental evidence and procedures developed in the laboratory and the field will have to remain unknown until the end of the war. Certain of the newer developments for arthropod control, however, are reflected in published accounts, particularly those concerning the control of mosquitoes that transmit malaria.^{1, 2}

Russell² has reviewed the various methods of controlling mosquitoes now in use among the armed forces, methods that he had a great share in developing and applying in the Philippines and India. The measures for military malaria control are applicable both to fixed installations, such as camps, and to field operations. In addition to the well-known methods of controlling mosquitoes by screening, the destruction of larvae and the use of sleeping nets, methods for the spray killing of adult mosquitoes

and keeping them away with repellents are now effective.

Methods for the spray killing of adult mosquitoes were given an effective trial in Africa by De Meillon³ and Ross.⁴ Since that time they have been widely used in India,⁵ and have been extremely successful in reducing the transmission of malaria.⁵ The spray for the disposal of the effective agent, extract of pyrethrum flowers, may be applied with small household spray guns and paint-gun sprayer assemblies or from pressure cans or cylinders. Application in the form of an aerosol from pressure cylinders is becoming increasingly useful both in the field and for effective spraying of aeroplanes arriving from tropical areas. Effectiveness against the tsetse fly,⁶ the vector of sleeping sickness, is particularly fortunate because of the great danger of introducing this insect to South America in much the same way as the highly efficient malaria vector, *Anopheles gambiae*, was introduced some years ago in Brazil.

The pyrethrum sprays are contact poisons, killing all species of mosquitoes and certain other insects by a destructive action on the central nervous system. These sprays are nontoxic to man and lower animals, although some irritation and inflammation may be caused by direct contact on the skin.

Mention should also be made of mosquito repellents, which are said to be effective for at least four hours. Two of these listed by Russell² are known as "612" (Everready) and dimethylphthalate (Skat).

Just how soon some of the above compounds will be released for civilian use will depend no doubt on the length of the war. It should be appreciated, however, that the war has stimulated research in a field that needed development, thereby helping in more efficient control of arthropod-borne diseases and also providing the civilian with an eventual means of alleviating suffering from the bites of the ubiquitous mosquito.

AWARD FOR VALOR

Major John W. Henderson, M.C., A.U.S., of Worcester, was recently awarded the Silver Star for gallantry in action near Alimena, Sicily, on July 22, 1943. The citation reads: "Besieging enemy forces had forced our troops to withdraw. Under cover of darkness, he successfully led a searching party well forward of the outposts to locate and evacuate casualties. His outstanding courage and coolness under heavy enemy fire merit the highest praise."

William D. Ducey of Brockton, because of gross professional misconduct in the practice of his profession as shown by his conviction in court.

REPORT OF MEETING

NEW ENGLAND PATHOLOGICAL SOCIETY

The first meeting of the year of the New England Pathological Society was held in the Amphitheater of the Mallory Institute of Pathology on Thursday evening, January 20.

The first paper was given by Dr. Maxwell Finland, the title being "Clinical and Physiologic Aspects of Conflagration Injuries of the Lungs and Air Passages." Respiratory complications of conflagration injuries, as judged from clinical observations in the cases from the Cocoanut Grove disaster, vary markedly in severity. The mildest cases may show nothing more than slight cough and irritation of the throat. The next grade of severity is manifested by laryngitis without evidence of pulmonary damage. Then there may be laryngotracheobronchitis, as evidenced by hoarseness, cough, sputum and scattered musical rales. Pulmonary involvement of varying extent is manifested by these signs and, in addition, by increasing numbers of rales scattered throughout the lungs and, later, by atelectasis of varying extent and by signs of small areas of consolidation. The severer cases have more extensive rales with proportionally greater degrees of dyspnea and cyanosis. In such cases, there usually is considerable stridor, which may be severe enough to necessitate tracheotomy or bronchoscopic suction of the larynx and trachea. Such suction is productive of thick mucoid material that may contain fibrinous membranous structures of varying size. The aspirated material also contains ciliated epithelial cells and many carbon particles.

Practically all cases with injuries to the respiratory tract also have burns of the face and nose. In general, the severity of the respiratory damage is correlated fairly closely with the extent and severity of the surface burns. In those cases from the Cocoanut Grove fire in which there was a great discrepancy between the extent of the surface burn and the severity of the respiratory damage, a story of some attenuating circumstance was usually discovered to account for discrepancy. For instance, some patients with extensive surface burns had covered their faces and noses with wet cloths and had avoided respiratory injury in that way; whereas those who were well clothed, or were stampeded and found themselves beneath other people, had extensive respiratory damage without surface burns.

No single cause of the respiratory injury could be determined. All the patients with the severest pulmonary damage had apparently had prolonged exposure after having become unconscious within the burning building, the loss of consciousness probably being due to excessive amounts of carbon monoxide. In this state the patients presumably inhaled hot noxious fumes that contained products of incomplete combustion of organic materials containing carbon and nitrogen. Some of these products are known to be pulmonary irritants. Interestingly enough large volumes of plasma, physiologic saline solution and other fluids were given to almost all the patients who had severe respiratory damage without apparently producing or increasing pulmonary edema to any appreciable extent. These studies were carried out with the collaboration of Dr. C. S. Davidson, of the Thorndike Memorial Laboratory, and Dr. Stanley Levenson, resident surgeon to the Burn Assignment of the Surgical Services, Boston City Hospital.

In the discussion that followed, the question of the clinical effect of nitrous oxide was raised. If this had been present, in Dr. Finland's opinion, the findings would have been similar to those seen in the Cleveland disaster, in which the patients exhibited more upper respiratory symptoms than those referable to the tracheobronchial tree.

The next paper was entitled "Pathology of Conflagration Injuries to the Respiratory Tract" and was given by Stanley Leary. He reported the findings in the Cocoanut Grove victims in the Pathological Department of the

CORRESPONDENCE

DEPRIVATION OF LICENSES

To the Editor: At a meeting of the Board of Registration in Medicine held on April 12 the Board voted to revoke the license of Dr. Matthias V. Bridges, 41 Buckingham Road, North Andover, Massachusetts, to practice medicine in the Commonwealth because of his conviction in court.

H. QUIMBY GALLUPE, M.D., Secretary
Board of Registration in Medicine

State House
Boston

To the Editor: At a meeting of the Board of Registration in Medicine held May 17, the Board voted to revoke the registration to practice medicine in this Commonwealth of Dr. Ray D. Hester, West Warren, Massachusetts, because of gross misconduct in the practice of his profession as shown by his conviction in court.

H. QUIMBY GALLUPE, M.D., Secretary
Board of Registration in Medicine

State House
Boston

To the Editor: At a meeting of the Board of Registration in Medicine held May 17, the Board voted to revoke the license to practice medicine in this Commonwealth of Dr. Lizzie Osgood, 42 North Street, Pittsfield, Massachusetts, because of a mental condition.

H. QUIMBY GALLUPE, M.D., Secretary
Board of Registration in Medicine

State House
Boston

To the Editor: At a meeting of the Board of Registration in Medicine held May 17, the Board voted to revoke the license to practice medicine of Dr. Ralph Coleman, 174 Central Street, Lowell, Massachusetts, because of gross misconduct in the practice of his profession.

State House
Boston

To the Editor: At a meeting of the Board of Registration in Medicine held May 17, the Board voted to revoke the license to practice medicine in this Commonwealth of Dr. Harry Weintraub, 327 Salem Avenue, Malden, because of gross misconduct in the practice of his profession as shown by his conviction in court.

H. QUIMBY GALLUPE, M.D., Secretary
Board of Registration in Medicine

State House
Boston

To the Editor: At a meeting of the Board of Registration in Medicine held May 17, the Board voted to revoke the license to practice medicine in this Commonwealth of Dr.

Hospital and of the Medical Examiner Service of Suffolk County at the Mallory Institute of Pathology. According to the studies of Mr. Frank Stratton and Dr. W. W. E. Jetter, the blood from 9 of 10 victims dying at the club revealed a saturation with carbon monoxide adequate to account for the deaths. In 6 victims who died at the club there was injection of the mucosa of the upper tract with punctate hemorrhages, as well as hemorrhagic edema of the widely distended lungs.

Among the hospitalized victims the outstanding symptoms were respiratory and were responsible for the high mortality. The lesions involved the upper tract and the terminal bronchioles, atria and alveoli. In the literature, the only similar conflagration injuries were reported from a German munition factory in 1917; this was associated with a flash fire with heavy smoke among women filling hand grenades, and the mortality was 50 per cent.

Lesions in the victims comprised minor visible burns, including the nares, and pseudomembrane formation in the larynx and upper trachea; there was less effect in the lower trachea but in some cases, necrosis of the bronchial walls and pseudomembrane formation was present. Lesions of the lung parenchyma were focal, but with hemorrhage and fibrin formation in most cases rather than purulent bronchopneumonia. The polymorphonuclear reaction was less than expected, as though negative chemotaxis was being exerted. Nonoccluding thrombi in veins were frequent. Occluding venous thrombi with infarcts were present in 3 cases. The victims who survived the first few days tended to show only slight lesions (injection and hemorrhage) of the upper tract; the lungs evidenced massive edema in some cases, but focal lesions of the terminal bronchioles and parenchyma were found in all dying within twelve days after the fire. The lungs in general were distended, atelectasis was not marked, the bronchi were dilated, air was trapped focally and there was less emphysema than expected.

Dr. Valy Menkin in discussing the paper stated that the findings were characteristic of the necrosin effect, with necrosis and fibrin thrombosis of veins. The liberation of eglobulin was, he thought, responsible for the bed fever. The absence of marked neutrophilic infiltration did not mean the absence of an acute inflammatory process but was a phenomenon of gradation. Possibly lactic acid formation prevented the emigration. Dr. Leary stated that, although the neutrophilic reaction was not the usual type of response, the lesion was nevertheless inflammatory in type. In response to a question by Dr. Reuben Z. Shultz concerning the type of injury seen in cases of immediate death, Dr. Leary said that death was due to carbon monoxide poisoning with injected overdistended lungs.

The last paper was by Dr. Alan Moritz and was entitled "An Experimental Study of Thermally Induced Injuries of the Lungs and Air Passages of Dogs." Dry and moist air at initial temperatures varying between 100 and 1000°C. was conducted to the larynx of anesthetized dogs through an insulated glass cannula. By means of an electrical heating unit, the inner wall of the cannula was maintained at a minimum temperature of between 100 and 125°C. to reduce heat loss between the external source of heat and the larynx. In some experiments the inhalation of hot air occurred incident to the normal respiratory activity of the animal, and in others hot air was forced into the lungs by a pump in such a way as to simulate the rate and amplitude of respiration. Thermocouples were placed in the larynx and at the bifurcation of the trachea to record the temperature of the inhaled air.

It was observed that moist air at 100°C. was more likely to produce pulmonary injury than dry air at 1000°C. Even with an initial external temperature of 1000°C., dry air was cooled to between 500 and 600° at the larynx and to between 60 and 80° by the time it reached the bifurcation of the trachea. The principal if not the only pulmonary changes produced by the inhalation of hot dry air were hypcremia and focal atelectasis due to the aspiration of detached masses of necrotic tracheal mucous membrane.

Superheated moist air (100 to 125°C.) produced direct pulmonary injury in the form of a necrotizing bronchitis with interstitial and intra-alveolar pneumonia of the central portions of all lobes, interstitial and intra-alveolar hemorrhage, and pulmonary edema.

In normal circumstances the inhalation of superheated air, dry or moist, would not be expected to produce significant pulmonary disturbance except in association with severe

burns of the skin and of the mucous membranes of the nose or mouth and an obstructive edema of the larynx. Primary injury not associated with burning of the skin of the face and of the mucosa of the nose and mouth, or with laryngeal edema, is not likely to be of thermal origin.

In response to a question concerning the length of exposure, Dr. Moritz said that with heated air, the exposures were up to 100 respiratory cycles over a period of four seven minutes. With steam, the exposures were approximately forty seconds. In answer to another question, he stated that the effect of hot air was greatest in the upper portion of the trachea, where the heat was given up most rapidly. There was also considerable discussion about the location of the edema of the larynx. In animals, Dr. Moritz found the picture to be variable, depending on the amount of areolar tissue present in the different areas. This tissue is especially loose on the esophageal surface of the larynx. Dr. Leary stated that, in his experience, the most marked edema in man was on the aryepiglottic folds.

BOOKS RECEIVED

The receipt of the following books is acknowledged and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Life Is Too Short: An autobiography. By C. Kay-Ser (Frederick Creighton Wellman, M.D.). 8°, cloth, 348 pp. Philadelphia: J. B. Lippincott Company, 1943. \$3.50.

This is an autobiography of a physician who went to Africa as a young doctor and remained there to study tropical diseases, compete with witch doctors, hunt big game, explore and survey where no white man had been before. From Africa, Dr. Wellman went to Europe and later to South America, finally returning to America.

A History of Tufts College Medical School. By Benjamin Spector, M.D., professor of anatomy and professor of the history of medicine, Tufts College Medical School. 8°, cloth, 414 pp., with 49 illustrations. Boston: Tufts College Medical School Alumni Association, 1943. \$5.00.

This history is fully documented and is illustrated with large number of appropriate pictures. An appendix contains photographs of the deans and the heads of the various departments of instruction, past and present, ninety-seven persons being included in this group.

1944 Daily Log for Physicians. Champaign, Illinois: Colwell Publishing Company, 1943. \$6.00.

This standard account book for physicians has been issued in its usual format for the year 1944. Of particular interest is the comparative income schedule, considered a short cut to accurate figures for income-tax purposes. The 1944 edition also contains a new form for nonprofessional deductions—that is deductible expenses that are personal in origin and should not be included in professional expenses.

A Surgeon's World: An autobiography. By Max Thore M.D. 8°, cloth, 410 pp. Philadelphia: J. B. Lippincott Company, 1943. \$3.75.

This is the autobiography of a successful surgeon who grew up in the Old World and made his mark in Chicago.

NOTICES

ASSOCIATION OF MILITARY SURGEONS

A meeting of the Association of Military Surgeons of the United States will be held at the Waldorf-Astoria Hotel, New York City, November 2 to 4. In addition to the Surgeons General of the Army, Navy, and United States Public Health Service and by other distinguished guests there will be formal papers, panel discussions and scientific and technical exhibits on the latest advances in military medicine.

THE MANAGEMENT OF A BLOOD BANK AT THE MASSACHUSETTS MEMORIAL HOSPITALS: THE NEW PROBLEM OF RH TYPING*

FRANK E. BARTON, M.D.†

BOSTON

IN 1938, the Massachusetts Memorial Hospitals established the first blood bank in Greater Boston. The great efficiency of this new procedure in providing blood for transfusions has resulted in its continued growth and development. In 1939 the use of placental blood for transfusions was reported.¹ In 1941 the methods followed in developing a blood bank in a large metropolitan hospital were given in detail² and a simplified citrate-dextrose blood preservative was described.³ In this article I wish to report the further progress of this blood bank in dealing with the new developments in blood typing, with special emphasis on the importance of Rh typing of all donors and recipients in the bank.

The Transfusion Service at Massachusetts Memorial Hospitals not only concerns itself with furnishing blood and plasma but is also responsible for determining the causes of transfusion reactions. In 1941 several reactions were encountered that could not be explained. Rechecking of the bloods of the recipients and donors failed to show any agglutination. By typing for the Rh factor, however, incompatibility in the blood types between recipient and donor was demonstrated and, in some cases, abnormal agglutinins were found in the patient's serum.

During 1940 and 1941, Levine,⁴ Wiener⁵ and Landsteiner⁶ published independently articles concerning hemolytic transfusion reactions encountered from the use of homologous blood that seemed to bear directly on our problem. Their conclusions are familiar and will not be dwelt on in any detail, since a complete review of the subject has recently been published by Diamond⁷ and by Hooker.⁸ Levine⁴ pointed out that a fatal transfusion reaction may result from the use of apparently compatible blood without any previous warning. He showed that Rh- patients are immunized or sen-

sitized to the Rh blood factor by gestation involving one or two Rh+ infants. Levine⁴ believed that the patient is immunized against an antigen unrelated to the blood properties A and B, which is present in the blood of the fetus but lacking in the patient's own blood. The fetus inherits the factor from the father, who is Rh+. The fetal red cells, being Rh+, build up antibodies in the Rh- mother, so that the first transfusion of an Rh+ blood may result in a hemolytic reaction. Since no warning of such sensitization and the development of anti-Rh agglutinins in the patient's serum can be obtained from a clinical examination or history, the situation is fraught with danger. Wiener⁵ also pointed out that isoantibodies for Rh, unlike those for Types A and B, do not normally occur in human plasma, and that the initial transfusion of Rh+ blood into patients who do not have isoantibodies for this agglutigen is ordinarily uneventful, the transfused cells surviving and functioning in the circulation for as long as three or four months. Subsequent transfusions of Rh+ blood, however, result in increasingly severe reactions.

Realizing that a well-organized blood bank should safeguard its patients from the possibility of such reactions, we felt obligated to carry out Rh typing in an efficient and active manner. In April, 1942, therefore, the Massachusetts Memorial Hospitals became a sponsor and member of the Blood Grouping Laboratory, an organization formed for the purpose of, and equipped for, typing for the Rh factor in human blood.

Record of Reactions.

During the past year 1169 flasks of blood have been collected and 1022 transfusions have been given. The percentage of reactions encountered was 6.4 per cent. The reactions are graded as follows: mild febrile reactions (99 to 101° F.) lasting but a short time following transfusion, with or without chills; febrile reactions (102 to 103° F.), with chills but without evidence of hemolysis; and

*From the Department of Surgery, Massachusetts Memorial Hospitals, and the Boston Blood Grouping Laboratory.
†Instructor in surgery, Boston University School of Medicine, visiting surgeon, Massachusetts Memorial Hospitals.

The next case is reported to emphasize the difficulties that may be encountered from incomplete typing. The Blood Grouping Laboratory, as already stated, was organized in April, 1942; this patient was admitted only a few days following that date. The value of Rh typing was not yet fully realized, which accounts for the following history and did more to educate the staff than any number of lectures would have done.

CASE 2. H. M., a 33-year-old woman, was admitted with the following past history of pregnancies: a 7-pound term baby in 1932; a 2-month miscarriage, with no known cause, in 1933; a 7 $\frac{3}{4}$ pound normal baby at 9 months in 1935; 3 $\frac{1}{2}$ -month miscarriage in 1936 and 1937; a 6-pound premature baby, which was alive at birth but later died of anemia, in 1939; and an 8-pound normal baby at 9 months in 1940.

During March, 1942, the patient reported to the Prenatal Clinic. The hemoglobin was 48 per cent and the red-cell count 4,000,000. She returned to the clinic on May 8 with a hemoglobin of 36 per cent and a red-cell count of 3,000,000. Because of this progressive anemia, she was admitted to the hospital for transfusion. She was reported as Type B and was transfused the following day with Type B blood from the blood bank, cross matching showing apparent compatibility. She immediately had a transfusion reaction, with a chill and fever. Soon after the reaction started, hemoglobinuria was noted and the patient developed jaundice. Sodium bicarbonate was administered intravenously. The original blood specimens were rechecked and were found by the usual technic to be still compatible. On May 9, the patient was found to be Rh-. Her husband was found to be Rh+. On May 10 the patient went into labor and delivered a small live baby whose size corresponded to that of an 8-month fetus. The baby developed anemia on the 4th day and was found to be Rh+, showing a slight amount of anti-Rh agglutinin. After transfusion the baby did well, and on discharge from the hospital it was gaining weight and the jaundice was clearing. The mother was given a transfusion of Rh- blood, without reaction. Her blood continually improved and she was discharged on May 23. Four anti-Rh determinations were made between May 19 and May 23. Immediately following the reaction the titer became markedly reduced, only to return to approximately its original strength on discharge. Later it subsided.

On March 29, 1943, the mother was again admitted to the hospital for surgery. Following operation it was necessary to transfuse her, and she was given Rh- blood, without reaction. The anti-Rh agglutinins present before this last transfusion completely disappeared.

The last case is reported simply to show the value of routine Rh determinations on all surgical cases that have a probability of repeated transfusions. If this patient had been unfortunate enough to have received Rh+ blood, he might have had a serious reaction with the third or fourth transfusion.

CASE 3. F. B., a 75-year-old man, was admitted to the Surgical Service on November 11, 1942, with a diagnosis of carcinoma of the stomach and prepared for a subtotal gastrectomy. Realizing that several transfusions might be required, the surgical staff had him typed and found him to belong to Group A and to be Rh-. He was given one preoperative transfusion and three postoperative transfusions with Rh- blood, without reaction.

SUMMARY

The methods employed by the Massachusetts Memorial Hospitals in dealing with the Rh factor in conjunction with its blood bank have been described.

To avoid hemolytic transfusion reactions and other untoward effects from the use of banked blood, it is pointed out that Rh typing is indicated for all surgical and medical patients when there is likelihood of repeated transfusions; for all patients with a history of previous reactions; for all patients who have received emergency transfusions without typing, before a second transfusion is given; for all obstetric cases, before admission, and all surgical deliveries; and for all babies born with jaundice and anemia.

It has been demonstrated that a practical and efficient method of carrying out Rh typing for all needed cases, especially in a hospital having an active obstetric service, is the organization of a blood-grouping laboratory, jointly sponsored by several institutions.

FUNCTIONAL VOMITING AS INTERPRETED BY AUSCULTATION OF THE ABDOMEN

NEIL C. STEVENS, M.D.

WALPOLE, NEW HAMPSHIRE

THE two types of vomiting, postoperative and periodic, discussed in this article rest on a functional basis. Both are frequently the result of spasm of the pylorus, with simultaneous relaxation of the fundus and inhibition of the cardia. These factors may be produced by a number of different causes, the most important being certain drugs and the condition of the nervous system. Fatigue, alcohol and dietary excesses also play a leading part.

Many physicians and surgeons fail to remember that spasm of the pylorus is the primary cause of vomiting in these functional conditions, and that acidosis and loss of fluids are the result and not the cause. Furthermore, the antispasmodic action of luminal sodium is not sufficiently appreciated, and one frequently overlooks the fact that this drug stops vomiting in the majority of such cases, usually within half an hour. No good results are obtained by giving it by mouth, since it either is vomited or fails to be absorbed. It must be given hypodermically and in fairly large doses, the first one being 5 or 6 gr. Usually one dose is enough.

If one makes a practice of listening to the abdomen of patients with functional vomiting, one finds that they are uniformly silent before any medication is given. The spasm at the pylorus seems to effect the motility of the entire bowel. Twenty minutes to half an hour after the administration of luminal sodium peristalsis begins, and almost immediately the nausea and vomiting cease.

POSTOPERATIVE VOMITING

Postoperative vomiting is of frequent occurrence. It not only may be exceedingly distressing to the patient but at times results in disaster, so far as the operation is concerned. It is more frequent in nervous, high-strung persons than in others. Its occurrence depends to a large extent on the preoperative sedative and the kind of anesthetic used. Morphine is the sedative preferred by most surgeons and the one most conducive to vomiting by its central emetic action. Many surgeons still do not realize that morphine causes, on the one hand, pyloric spasm and, on the other, hypermotility of the small intestine. The net result is an irritable bowel, which together with the shock of the operation frequently produces postoperative vomiting. If luminal sodium were always used in large doses, both preoperatively and postoperatively, the incidence of vomiting and gas pains would be reduced to a minimum. Contrary to the prevailing belief, gas pains are due to a collection of gas not in a dilated, flaccid bowel but in a hypertonic and spastic small intestine. Morphine and other stimulants of the motor function of the bowel, although they

may produce a temporary relief, in the end aggravate and prolong the trouble.

Illustrative of the type of case under discussion is the following.

A 50-year-old woman had a hysterectomy and vaginal repair and was given $\frac{1}{4}$ gr. of morphine preoperatively. The anesthetic was ether. The operation was uneventful. After coming out of the anesthetic the patient vomited and continued to do so for the next 24 hours. During that time, 3000 cc. of 5 per cent glucose solution was administered intravenously and $\frac{1}{2}$ gr. of pantopon was given at 4-hour intervals, but the nausea and vomiting continued unabated. Oxygen was administered, but it had only a temporary beneficial effect. On the evening of the day following the operation, I was called to see the patient. Except for the intense nausea and vomiting, she seemed to be in good condition. The temperature, pulse and respirations were practically normal. The abdomen was not distended and was completely silent on auscultation.

With the permission of the surgeon who had performed the operation, 5 gr. of luminal sodium was given intramuscularly. No other medication was administered. Twenty minutes later the first peristaltic sounds were heard, and 5 minutes after that the patient felt better. The nausea stopped and there was no further vomiting. One half-hour following the administration of the luminal sodium she asked for something to eat.

There is nothing unusual about this case, except that the nausea and vomiting were intense and prolonged. Countless other similar cases are due to the same causes — the shock of the operation, the anesthetic and the administration of morphine or pantopon or any one of these. Having listened to the abdomen of many such patients, I believe that the chief cause is a spasm of the pylorus, which permits no gas or contents to pass from the stomach into the intestine. The evidence for this point of view is that no peristaltic sounds are heard so long as nausea and vomiting persist, and that after the administration of luminal sodium, usually twenty minutes, peristaltic sounds are heard and nausea and vomiting disappear.

PERIODIC VOMITING

Periodic vomiting is a frequent condition during the first decade of life, especially in nervous, high-strung children. Adults, especially neurotic women, are also subject to it. It is in all probability a functional condition. It may or may not be associated with attacks of migraine and it may come at regular or irregular intervals. There is apt to be more regularity in the periodic vomiting of children than in that of adults.

The apparent cause of periodic vomiting is a neurotic background. The attacks, which are often precipitated by nervous tension, emotional upsets, fatigue, overindulgences in diet and overexertion, last for a few hours or a few days, and usually subside after the attack has passed.

The onset is usually without much warning, often following a hard day's work or an emotional crisis. The vomiting is apt to be frequent and severe. If the stomach contents have been expelled and the stomach has been at rest for a while, any attempt to take solids or fluids is almost sure to precipitate another attack. It is useless to give medicine by mouth in these cases, since it is never retained.

Except for the abdomen, the physical examination is usually negative. The abdomen is slightly spastic and somewhat tender, owing to strain on the abdominal muscles. It is silent on auscultation and may remain so for long periods except for an occasional tinkle. There is in all probability an intense spasm of the pylorus that is transmitted over the entire length of the small intestine. So long as the spasm lasts, the vomiting continues.

The treatment for this condition varies a good deal. Excellent results have been obtained with luminal sodium given hypodermically. As much as 6 to 10 gr. every twenty-four hours may be given. It may be necessary to repeat this dosage in the second twenty-four hours, but in my experience only one patient, whose case is discussed below, failed to respond within twenty-four hours. Luminal sodium relieves spasm and slows the peristaltic rate. The following case illustrates the condition and its treatment.

A 35-year-old woman, the mother of two children, began to have attacks of periodic vomiting when she was 20 years of age, after the first child was born. For 15 years she averaged about three attacks a year, each in her opinion due to fatigue or an emotional upset. She had had repeated examinations, including several series of x-ray examinations of the stomach and intestinal tract. Nothing abnormal was found. When the attacks first began, they were extremely severe and lasted from 1 to 2 weeks. At the beginning, vomiting was frequent, occurring every half-hour or every hour, and the patient was unable to retain anything. When she attempted to take fluids of any kind, they were immediately vomited.

The last attack of vomiting occurred in October, 1941. The patient had been working hard and was extremely tired before it started. It began with the same intensity as had the other attacks. When I was called, she had been vomiting continually for 24 hours, and even turning over in bed caused vomiting. Treatment during previous attacks had consisted of gastric lavage, the intravenous administration of 5 per cent glucose solution and the hypodermic injection of a solution consisting of hyoscine, morphine and extract of cactus. On the patient's request this treatment was continued, although it was not thought that the hypodermic injections were indicated. For 3 days, no beneficial results accrued. The vomiting continued unabated, and the patient rapidly lost weight and strength.

On the 4th day, large doses of luminal sodium were given subcutaneously—4 gr. every 6 hours. This was kept up for 2 days. On the 2nd day of this treatment, the patient still vomited, but at less frequent intervals, and the return of peristalsis was noted. On the following day,—the 6th day of the attack,—she was much improved. Vomiting stopped and she was able to take fluids without nausea. Thereafter she continued to improve.

For the past 22 months, the patient has been in good health. She has been taking two $\frac{1}{2}$ -gr. tablets of luminal sodium twice a week to allay the irritability of the stomach and nervous system and to prevent a recurrence of the attacks.

Only 6 cases of cyclic vomiting in children have been studied, but these were so similar in their history, symptomatology, physical findings and response to treatment that one may be hopeful that the underlying principle in these cases will hold true in a much larger group. All 6 children were between the ages of three and eight years at the time they were seen. All were nervous, and at least one parent of each child gave evidence of nervous instability. The parents of one patient were heavy drinkers and had been for several years preceding its birth. The symptomatology was much alike in all the cases, with vomiting once or twice a month and sometimes oftener, usually precipitated by fatigue, nervous tantrums or the consumption of indigestible food. Every patient was below normal weight. During prolonged attacks, acetone was present in the urine. Marked and persistent hypermotility of the bowel was the physical finding common to all cases. One of these patients, a boy four years of age, did not improve under treatment, and it was not until a pair of large, diseased tonsils had been removed that he began to do so. For the last two years his vomiting has practically ceased.

The following case is quite typical.

A 6-year-old girl had never been in good health, and her mother could not remember when she did not have periodic attacks of vomiting. When first seen, she was a pale and asthenic child and 11 pounds underweight. She had had an attack of vomiting about once a month, occasionally at shorter intervals, that lasted about three days; each caused extreme weakness and required 2 days' rest in bed to regain strength. Physical examination was normal except for evidence of extremely active peristalsis. For the previous 3 years, the patient had been under the care of a New York pediatrician, who had unsuccessfully tried many diets.

She was first seen during an attack of vomiting. One grain of luminal sodium was given intramuscularly, and thereafter about $\frac{1}{8}$ gr. of luminal sodium was given by mouth three times a day for 3 days. The dose was then reduced to $\frac{1}{4}$ gr. This was continued for a week and at intervals during the next 6 months. On only a few occasions since then has she had any of the drug. She has now had no attacks for 3 years, except one following "grippe." Up to a year ago, she had gained 15 pounds in weight, was going to school, played games and was apparently a normal child.

SUMMARY

Functional postoperative vomiting and periodic vomiting are in all probability largely due to spasm of the pylorus. So long as the vomiting continues, the abdomen remains silent. A few peristaltic sounds are sometimes heard at intervals.

Luminal sodium given hypodermically in large doses relieves the spasm and almost always stops vomiting. Peristaltic sounds are usually heard within half an hour after its first administration.

PRACTICAL DETAILS IN THE MANAGEMENT OF STERILITY, WITH SPECIAL REFERENCE TO ENDOCRINE FACTORS*

SAMUEL R. MEAKER, M.D.,† CHARLES H. LAWRENCE, M.D.,‡ AND SAMUEL N. VOSE, M.D.§

BOSTON

THE emotional tension of wartime and the accompanying social and economic upheavals promptly reflect themselves in outworkings of the reproductive instinct. Thus are created new and larger problems of prostitution, venereal disease and illegitimacy. Thus also new demographic trends appear, notably affecting marriage, divorce and the birth rate. In 1942 this country attained an all-time record of 3,000,000 births, the highest peak of the curve coming ten months after Pearl Harbor. At the same time there has been a great increase in the number of patients seeking the relief of barrenness. It therefore seems opportune to survey the present status of the investigation and treatment of involuntary sterility, and to define those lines of procedure that have proved to be most useful in clinical practice.

CAUSATION OF STERILITY

In order to obtain the best results in the management of sterility, one must appreciate clearly the general principles of causation, which are three in number.¹ First, clinical cases of sterility are due almost without exception to multiple causes. The average such mating presents four or five demonstrable factors of infertility. In a minority of cases some one factor predominates, in the sense that it is serious enough by itself to prevent conception. Oftener the causative mechanism is a combined action of several milder factors, each of which lowers fertility to some extent and all of which together produce a sterility that is relative rather than absolute. Second, in more than 80 per cent of cases these multiple factors are divided between the husband and the wife. Thus, it is comparatively uncommon to find that the fault lies entirely with one partner. In the aggregate, the sum totals of male and female responsibility are about equal. Third, constitutional disorders, both endocrine and non-endocrine, play a large part in the causation of human infertility. In the male they are considerably more important than are local abnormalities of the genital organs.

DIAGNOSTIC STUDY OF STERILE MATING

From what has been said about etiology, it follows that every sterility problem ought to be surveyed

from four viewpoints — urologic, gynecologic, medical and endocrinologic.¶ A basic routine should be followed, with supplementary examinations made on special indication. Complete study is essential to reveal all the causative factors present and so to permit a therapeutic attack from all possible angles. Procedure on this basis has more than doubled the number of successful results obtained. It would be sadly inadequate in sterility cases to accept the first abnormality discovered as the sole and only cause, on the unwarranted assumption that other faults do not coexist.

UROLOGIC MANAGEMENT

The urologist takes a history and makes a careful examination of the male reproductive organs. In a small number of cases these steps in the investigation reveal major obstacles to fertility, such as impotence, testicular atrophy and blockade in the epididymides. Oftener the examiner discovers conditions of comparatively minor importance. The most frequent finding is chronic prostatovesiculitis. This disorder was formerly considered to be a leading cause of male sterility because of the fact that the spermatozoa, after leaving the testicles, come into contact with bacteria and pus. Our experience has been that prostatovesiculitis, like any other chronic focal infection, contributes to infertility principally by elaborating toxins that pass into the blood stream and depress spermatogenesis.

In complete azoospermia, fortunately comparatively uncommon, it becomes necessary to distinguish between inactivity of the seminiferous tubules and bilateral obstruction of the epididymides. Puncture and aspiration of the testicle have been used to make this differential diagnosis. A better method is testicular biopsy, which gives precise information about the functional condition of the germinal epithelium. If adequate spermatogenesis is found to be going on and if spermatozoa are present in the epididymides, the operator may proceed to perform an epididymovasostomy. Although this operation succeeds in only a minority of cases, it offers the only chance of remedying an otherwise hopeless situation.

The critical examination of semen has contributed more to the successful management of sterility than has any other detail of modern progress. With cer-

*Read at the annual meeting of the Essex North District Medical Society on May 10, 1943.

‡Assistant professor of medicine, Tufts College Medical School; physician-in-charge, Endocrine Clinic, Boston Dispensary.

§Professor of genitourinary surgery, Boston University School of Medicine, urologist, Massachusetts Memorial Hospitals.

¶In 1927 we organized the first systematic group study of sterility with the collaboration of the late Dr. A. W. Rowe. The data which is originally used by us are reported in "The sterility of the male: a study of the last ten years experience has shown that it can be limited to the testicular ability. Certain of our patients in endocrinology have been treated by these methods and therapeutic approaches."

tain reservations, it may be assumed that a quantitative estimate of male fertility is afforded by the mathematical evaluation of the spermatozoa on the four counts of number, morphology, motility and endurance. An average normal specimen contains 100,000,000 spermatozoa per cubic centimeter; 80 per cent of these are mature and well formed; 75 per cent exhibit lively motility; and under favorable conditions of temperature and moisture they remain active for the better part of twenty-four hours. If a specimen falls notably short of these standards in any respect, some degree of infertility is indicated. An excess of morphologic faults is a finding of the greatest significance, since it strongly suggests a constitutional disorder. Unfortunately, only a minority of urologists make a practice of evaluating seminal morphology, and in consequence innumerable cases of male infertility go unrecognized. This point is so important that it deserves illustration.

CASE 1. Mr. and Mrs. A had been married for 6 years and involuntarily sterile for 5. The wife presented no serious obstacle to fertility. The husband's semen showed a sperm count of 60,000,000, with 32 per cent abnormal forms, a motility of 70 per cent and an endurance of 10 hours. There was nothing grossly wrong with his genital organs. He was referred back to his family physician with the recommendation that he be further studied from the medical and endocrinologic viewpoints. The physician elected to send him to a urologist, a man eminent in his field but without special experience in sterility. The consultant reported that the patient was free from prostatovesiculitis, that his semen contained large numbers of active spermatozoa and that he might therefore be regarded as perfectly fertile. This opinion prevailed. The wife was subjected to a useless curettage, and is now, I believe, receiving vitamin E. She has not conceived nor, unhappily, is she likely to do so.

By way of contrast, a case is cited in which a similar problem was handled intelligently.

CASE 2. Mr. and Mrs. B had been married and involuntarily sterile for 3 years. By a former marriage the husband had a son 8 years old. The referring physician reported that the wife's uterus was retroflexed and contained a fibromyoma as large as a hen's egg and that the husband's semen appeared excellent. A complete investigation of the couple was carried out. Insufflation of gas showed the tubes to be patent, and postcoital examination demonstrated that spermatozoa had reached the cervix; thus both of the uterine conditions were proved unimportant as factors of infertility. The semen had a sperm count of 72,000,000, with 34 per cent abnormal forms, a motility of 75 per cent and an endurance of 24 hours. No local genital lesion was demonstrable. Constitutional study of the husband identified chronic dental infection, poor hygiene, and mild hypothyroidism. He was treated; his wife was not. The abnormal forms diminished to 23 per cent. Two months later the wife conceived, and she is now approaching the end of an uneventful pregnancy.

Pregnancy has followed improvement in seminal morphology in so many cases that one may justifiably assume a cause-and-effect relation. A detail of Case 2 worthy of emphasis is the fact that the husband, the responsible partner in this sterile mating, had been able to produce a conception nine years previously. Individual fertility levels are not constant but undergo continual fluctuations. This is easily demonstrated in male patients, in whom conspicuous changes for the better or for the worse may occur within a few months.

GYNECOLOGIC MANAGEMENT

An adequate gynecologic survey of the infertile woman includes the following items: history, abdominopelvic examination, measurement of the uterine index, study of the endocervical secretions, postcoital examination, a test of tubal patency and the taking of a specimen for endometrial biopsy.

Certain details of the gynecologic history acquire special importance when the complaint is sterility. Among these are duration of marriage, use of contraception and pregnancies, if any, with their outcome. Inquiry about the sex life sometimes reveals such infrequency of intercourse that on this count alone the chances of conception would be small. Normal menstrual behavior usually means that ovulation occurs, although exceptions are not uncommon; abnormalities are worthy of close attention as possible indications of ovarian malfunction. Perhaps a third of observant women report periodic midmenstrual phenomena, such as brief spotting, leukorrhea and *Mittelschmerz*; these symptoms presumably coincide with ovulation. Information should be obtained about previous investigation and treatment for sterility, as well as about pelvic and abdominal operations of any sort. Two recent patients took treatment for years in the hope of conceiving, unaware of the fact that they had undergone bilateral salpingectomy.

Positive findings on abdominopelvic examination must be specially evaluated with regard to their effect on fertility. Many gross lesions, notably the majority of uncomplicated retrodisplacements of the uterus, are unimportant from this point of view. On the other hand, conditions ordinarily trivial, sometimes become highly significant in sterility cases. Chronic Skene's adenitis indicates old gonorrhea, with the ever-present possibility of tubal occlusion. Stenosis of the external os and strictures of the cervix may prevent free drainage of the endocervical secretions. Stigmas of hypoplasia are often in evidence, particularly in the form of a cervix that is long, conical and anteflexed. Polycystic ovaries represent the result of faulty ovulation in the past and at the same time offer an impediment to normal ovulation in the future.

Some years ago, one of us (S. R. M.³) defined the uterine index, a quantitative measure of the differential development of the uterus based on the relative lengths of corpus and cervix. In a completely infantile uterus the index is 0.25; in the mature organ it is 0.75 or higher. True infantilism is rare, although many practitioners have the habit of making this diagnosis whenever the uterus seems small; but lesser degrees of female genital hypoplasia frequently present themselves, and are clinically important because of the fact that underdeveloped ovaries produce few if any highly fertile ova.

The endocervical mucus must afford an environment favorable to spermatozoa if they are to reach

the upper genital tract in good condition. It normally undergoes a cyclic variation in consistence, being rather thick and viscid through most of the month but becoming thinner around the time of ovulation. Congestion, inflammation and faulty drainage may lead to the formation of an inspissated mucous plug that entangles and kills the male cells. In such cases pregnancy is sometimes made possible by such simple measures as the passage of a sound, precoital clearing of the cervix and the use of heat. When the trouble is more obstinate it may require cauterization, conization with the high-frequency current or a slight plastic operation to enlarge the external os and provide freer drainage.

For postcoital examination the wife reports two hours or less after intercourse. Microscopic study of the cervical contents shows the presence or absence of spermatozoa and the condition of those present. The special value of this test lies in the information that it affords as to normal delivery and reception of the male cells. It also gives direct evidence of the favorable or harmful effect of the endocervical environment. The recovery of living spermatozoa from the cervix indicates that the husband possesses at least some degree of fertility, but does not suffice to permit the necessary quantitative evaluation. The findings of postcoital examination should always be correlated with the results of direct examination of the semen.

There are two standard methods of testing the patency of the tubes: transuterine insufflation of gas and transuterine injection of iodized oil, followed by x-ray. Each of these has its particular advantages. Insufflation gives more information about the functional condition of the tubal musculature, whereas hysterosalpingography is superior for the demonstration of structural conditions and for distinguishing unilateral from bilateral patency. It is generally good practice to do insufflation first, reserving oil injection for those cases in which the tubes are not normally patent to gas. Apparent blockades sometimes disappear when chronic passive congestion is relieved by the use of heat or when a retrodisplacement is corrected. Both insufflation and injection have therapeutic as well as diagnostic value: they are indicated in mild obstructions, in occlusions unsuitable for operation and as a detail of the aftercare of salpingostomy.

There is, unfortunately, no test that demonstrates conclusively whether ovulation has occurred. Indirect evidence may be obtained by any of half a dozen techniques, of which endometrial biopsy is the most practical. By a simple office procedure a small sample of endometrium is taken not longer than three days before the beginning of a menstrual period. If the specimen shows a normal secretory phase, one may conclude that the ovary contains an active corpus luteum, presumably the result of a recently ruptured follicle. Such a finding does not, however, prove that a highly fertile ovum has been

liberated. In cases in which the premenstrual endometrium fails to exhibit a physiologic secretory phase, there is strong reason to believe that the cycle just ending has been anovulatory.

The surgical treatment of female infertility includes procedures of three general sorts. Mention has been made of dilatation and of tracheloplasty for the purpose of improving drainage of the endocervical secretions. Operations to restore tubal patency may be undertaken with a fair hope of success, provided that cases are carefully chosen and that the aftercare is skillful.⁴ Conservative surgery of the ovaries, notably the removal of retention cysts and persistent corpora lutea, is sometimes necessary to make ovulation possible. Two other procedures should be mentioned only to be condemned. Suspension operations are irrational unless malpositions of the uterus are complicated by conditions demonstrably unfavorable to conception; they ought never to be performed except after a therapeutic trial of reposition and use of the pessary. Curettage of the endometrium as commonly practiced is not only valueless as treatment for sterility but sometimes harmful.

There is still a widespread misconception among both physicians and laymen about the indications for artificial insemination with the semen of the patient's husband. The general impression seems to be that this is a procedure of last resort, to be tried when other methods of treatment have failed. As a matter of fact, artificial insemination offers no advantage whatever over sexual intercourse in cases where spermatozoa are naturally delivered to the cervix and there encounter a favorable medium. Its utility is therefore limited to the treatment of such comparatively uncommon disorders as hypospadias, impotence, vaginismus and intractable hostility of the endocervical mucus. On the other hand, insemination with donor semen, now coming more and more into favor, provides a remedy for childlessness in that large group of matings in which the husbands are incurably sterile.

MEDICAL MANAGEMENT

Stock breeders have always found it profitable in terms of dollars and cents to pay attention to the general physical well-being of their flocks and herds. In the old days physicians made a point of giving similar care to their sterility patients. With the featuring of complicated modern techniques of investigation and treatment, this simple aspect of management has become neglected. It should receive more consideration, for the proper functioning of the gonadokinetic mechanism depends in no small measure on sound health and good hygiene.

Complete study of cases brings to light a high incidence of certain constitutional factors of infertility. One of the commonest of these is poison-chronic focal infection of the teeth, nasal sinuses. Chemical poison,

example, lead and alcohol — fall into the same category. Debilitating diseases of all sorts are important, particularly the milder grades of anemia frequently encountered. Among dietary faults inadequate protein intake easily holds first place; avitaminosis is occasionally found. Sterility patients are often underexercised and in consequence suffer from the effects of a sluggish metabolism. Many of them, especially men, are victims of overwork, nervous tension and the general complex created by the artificial conditions of modern civilization.⁶

It is clinically demonstrable that disorders of the sorts just mentioned depress human fertility, sometimes severely. The practitioner who seeks and treats them as routine will accomplish not a few cures impossible by other means.

ENDOCRINOLOGIC MANAGEMENT

Physicians have come to believe that the results of endocrine treatment of infertility are generally disappointing. Many of the physiologic responses obtained in laboratory animals fail to manifest themselves with the same regularity in human beings. Optimistic claims made for new hormonal preparations prove to be exaggerated. Moreover, glandular therapy as commonly practiced in sterility cases can scarcely be expected to bring any great measure of success, since oftener than not it means simply the haphazard giving of "shots" on insufficient indications.

Although the efficacy of present-day endocrinologic methods admittedly leaves much to be desired, the fact remains that in certain types of cases the judicious use of potent glandular preparations increases fertility to the point where conception becomes possible. To accomplish such results the practitioner must have the best possible idea of the endocrinopathic states responsible for infertility and of the lines of procedure that offer a reasonable chance of correcting these disorders. He should also bear in mind that there are two important prerequisites to successful endocrine therapy. First, coexistent nonendocrine factors of infertility must be eliminated. Measures to stimulate the ovaries are obviously futile if the wife's tubes are closed or the husband has azoospermia, and yet an immense amount of treatment fully as irrational as this has been administered. Second, conditions inhibiting normal endocrine function should be removed. Under this heading come local impediments to ovulation, such as retention cysts, and in both sexes any type of depressing constitutional state, particularly toxemia from chronic focal infection.

Since the chief aim of opotherapy in sterility is to improve the production of spermatozoa or ova, it is worth while to review briefly the endocrine mechanism that controls gametogenesis. Among the several hormones supplied by the anterior lobe of the pituitary gland there are two, or possibly two phases of the same hormone, that are gonado-

tropic or gonadokinetic in the sense that they stimulate testicular and ovarian function. In the male these hormones maintain the activity both of the seminiferous tubules and of the interstitial cell of Leydig. The interstitial cells in their turn elaborate the androgenic or male sex hormone, testosterone. In the female the pituitary gonadotropic hormones bring about cyclic ripening of follicle and formation of corpora lutea. The ovarian follicle secretes the female sex hormone, estrin; the corpus luteum produces estrin and progesterone. Both testosterone and estrin have the property of limiting or checking the secretion of gonadotropins; thus a pituitary-gonad balance is established. To a certain extent this balance is dependent on the proper functioning of other endocrine glands, notably the adrenal cortex, the islands of Langerhans and the thyroid gland.

The four endocrine disorders that figure most prominently as factors of human infertility are hypogonadotropism, male hypogonadism, female hypogonadism and hypothyroidism.

Hypogonadotropism

An insufficiency of pituitary gonadotropic action during adolescence results in some degree of genital hypoplasia, with permanent anatomic stigmas and functional impairments that can seldom be corrected after the end of the plastic age. Hypogonadotropism occurring in adult patients leads to an underfunction of the testicles or ovaries that provided that these organs are essentially normal often responds to treatment.

It is not easy to make a precise diagnosis of the gonadotropic insufficiencies that usually present themselves in sterility cases. In men and non-pregnant women the urinary output of the hormones in question is so small that assays are not very helpful. Blood-serum assays may be more informative. If all other causes of poor spermatogenesis can be ruled out, such findings as oligozoospermia and defective morphology may be presumed to indicate either subnormal stimulation of the seminiferous tubules or subnormal responsiveness, both of which conditions suggest the need of a stronger gonadotropic effect. Similarly in women one arrives at a diagnosis of hypogonadotropism indirectly, on the basis of evidence of poor follicular function obtained from endometrial biopsies, pregnanediol determinations and vaginal smears. In both sexes a proper therapeutic test often serves to confirm the presumptive diagnosis.

For purposes of treatment there are available preparations of the pituitary glands of animals and anterior-pituitary-like substances of chorionic origin derived either from the urine of pregnant women or from the blood serum of pregnant mares. All these must be given parenterally, since their active principles are destroyed by trypsin. Each of them is reported to have accomplished good results in

cases of deficient spermatogenesis.⁶ As to their effect on the ovaries, they have somewhat different properties. Pituitary gonadotropins tend to ripen follicles, whereas the chorionic hormones are predominantly luteinizing. For this reason it is often advisable to use these preparations in some sort of combination. Excessive dosage should be avoided, since it may produce atresic follicles and other degenerative changes.⁷

In theory, gonadotropic therapy ought to be a specific remedy in that considerable group of cases in which deficient gametogenesis is due to pituitary underfunction. In practice, results have not come up to expectations, but successes are frequent enough to warrant the use of this method when rational indications for it are present.

Male Hypogonadism

Hypogonadism in adolescent boys interferes with the development of the secondary sex characteristics. When the secretion of testosterone drops below the normal level in adult men, other results appear. There is sometimes loss of sexual desire and potency. A more constant effect is depressed functioning of the epididymides, prostate gland and seminal vesicles.

Testosterone insufficiency may be demonstrated by absence from the urine of the degradation product androsterone. The semen is likely to be reduced in volume and to exhibit increased viscosity. The most frequent spermatozoic defects in such cases are diminished motility and short duration of life, if not complete necrospemia. Other types of poor semen, notably those with oligozoospermia and abnormal spermatozoa, are seldom if ever caused by a lack of androgenic hormones.

From the foregoing facts it follows that there are two main indications for testosterone therapy in sterility. First, androgens are valuable in impotence when this disorder is directly caused by hypogonadism. The physician should, however, bear in mind that in most cases impotence is primarily of psychic origin. Second, decreased spermatozoic vitality and thick, scanty semen indicate the need for physiologic stimulation of the epididymides and accessory glands. When androgenic treatment is undertaken it is usually advisable to give gonadotropins also, to offset the tendency of the gonadal hormones to check or inhibit the function of the anterior lobe of the pituitary gland. Without this precaution there is considerable risk of depressing spermatogenesis.

Female Hypogonadism

Inadequate secretion of estrin at the time of adolescence prevents the full development of secondary sex characteristics. In mature women a lack of estrin or progesterone, or both, produces a number of effects, in particular pathologic muscular and epithelial reactions in the tubes, uterus

The uterine disturbances may lead to abortion, as well as to various menstrual disorders, but as a factor of sterility in the sense of inability to conceive, female hypogonadism plays a relatively minor role. This endocrinopathy is a result, rather than a cause, of abnormal ovarian behavior.

Urine assays afford quantitative information concerning the excretion of the derivatives of estrin and of progesterone; in cases of the more obscure type these tests are worth the difficulty and expense entailed. Ordinarily one depends on vaginal smears to reveal estrin deficiency, and on endometrial biopsies to show insufficiency of progesterone.

The chief practical uses of estrogens in sterility, however, are not for replacement therapy in demonstrable underfunction of the ovaries, but rather for specific stimulation of the tubes and uterus. Thus, good results have been obtained in tubal obstructions, both hypoplastic and inflammatory.⁸ Thus also, whenever any marked degree of genital hypoplasia is present, a course of estrogenic treatment may advantageously precede attempts to stimulate ovulation by the administration of gonadotropins.⁹ For these purposes diethylstilbestrol and the various biologic preparations appear to be equally satisfactory. In no way, either as replacement or as stimulation, can ovarian therapy logically be expected to improve oögenesis. Nevertheless, by some mechanism imperfectly understood, cyclic estrin-progesterone treatment of certain menstrual derangements, notably amenorrhea and anovulatory bleeding, is not infrequently followed by conception.¹⁰

Hypothyroidism

It is a well-established fact that in both sexes underactivity of the thyroid gland, even of slight degree, exerts a markedly depressing effect on fertility. The mechanism may be either a secondary upset of the pituitary-gonad balance or the harmful influence of a sluggish metabolism on the germ plasma. Whatever the explanation, clinical experience proves that an adequate level of thyroid function is one of the requisites of good spermatogenesis and oögenesis.

Routine examination of infertile patients reveals a considerable incidence of hypothyroidism. Many of these patients have low metabolic rates, slow pulses and subnormal temperatures but are free from the more conspicuous signs and symptoms of their disorder. They are energetic and alert and not overweight, and in general present nothing of the typical myxedemic picture. The semen often shows oligozoospermia or a high percentage of abnormal forms.

It should be remembered that a low metabolic rate is not by itself proof of hypothyroidism, and that treatment, instituted on this sole indication may be useless or even harmful. But when the diagnosis is properly established other

of infertility are ruled out, replacement therapy, with periodic checks to regulate dosage, gives remarkably satisfactory results.

SUMMARY

Some forty or fifty abnormal conditions are now recognized as obstacles to human fertility. These include constitutional depressions as well as disorders of the reproductive organs. In the typical clinical case of involuntary sterility several of these factors are present, and they are usually divided between the husband and the wife. This paper discusses the methods of complete diagnostic study prerequisite to any well-organized plan of treatment.

BOSTON MEDICAL LIBRARY

Report of the Librarian*

THE Library passed through its second year of our participation in the war, unbombarded, unwept and almost unsung. The trustees carried their burden with fortitude; the librarian made a moderate effort to use his budget appropriately; and the director and staff continued to serve the fellows and the public in the standards so long established. Slowly, as many of our more active members, the young men and women in the full bloom of their inky careers, went into the services or were called for more arduous and time-consuming hospital or teaching jobs, attendance fell off to one third and the use of our books, periodicals and pamphlets decreased by an almost equal amount, when compared with the figures for 1942. So, too, did inter-library loans. We were not actually hibernating, but our activities were somewhat slowed down in relation to the number of people we served daily. Within the Library itself, however, work went on at an even increasing pace. We tried to catch up on cataloguing and, although only 2000 new items were added to the Library in 1943, 15,000 catalogue cards were written, thus finally making available to our readers hundreds of volumes, not previously classified and catalogued. Much time was given, moreover, to our duplicate material, the director being only too glad to have a few extra moments for this important work. We were fortunate in receiving a considerable number of physicians' libraries as gifts during the year. This welcome material means to the director and his staff careful checking for items that we do not have, comparing all duplicates with our copy in order to retain the best and discard the old, classifying and cataloguing the new accessions and finally putting the items into

circulation. Thus a personal library, donated by a physician or his heirs, is integrated into our collections. In this way our library was largely built up in the past and our shelves are filled, as you well know, with the personal books formerly owned by past members. Such is the natural growth of a library such as ours, for the deeds of good men live after them in our overflowing stacks.

The rate of use of our collections remains about the same from year to year, although the quantity is less as the war proceeds. The 6000 readers of all types in 1943 used slightly more than four items apiece. Members, however, averaged eight items per individual for home use and about fifteen for use in Holmes Hall. Such figures are of little value for meticulous analysis, since many members did not use the Library at all. The estimates go to show, however, much to the satisfaction of the librarian, that the Library is used perhaps more extensively than many of our colleagues realize.

BOOK-REVIEW DEPARTMENT

The war has caused some changes in book reviews. Fewer long reviews can be published in the *New England Journal of Medicine* owing to restrictions of space, and fewer reviewers, particularly the younger men who often were actively engaged in research and the writers of books in their specialties before the war, are available. To ease the situation, an excellent compromise has been made; as each book is received, a brief description of its contents, usually limited to six or eight lines, accompanies the listing under "Books Received." In addition, certain books are selected for more extensive critical appraisal by competent reviewers, whose names are published in each index number of the semiannual volumes of the *Journal*. In 1943, seventy-eight

*Read in part at the annual meeting of the Boston Medical Library, March 7, 1944. The full report will appear in the *Sixty-Eighth Annual Report of the Boston Medical Library* (Boston, 1944).

physicians furnished one hundred and forty-six reviews. The quality of the work seems to the librarian to be uniformly good, for men chosen for this combined service to the *Journal* and the Library are among the outstanding members of the medical profession. The librarian, moreover, is fully convinced that their reviews are sounder because they are unsigned. So long as the quality of the group of reviewers is maintained, even the most sensitive author has little reason to complain of their unbiased and natural sentiments. The librarian has yet to see a grossly unfair or overpersonal book review in the *Journal*. He only wishes more reviewers would add punch to their blows! There are far too much slipshod writing, inconsequential changes to make a "new edition," and poor publishing in medical literature.

Occasionally a book is reviewed in the editorial columns of the *Journal*, particularly contributions of local interest or of outstanding value as distinctive additions to medical advancement. Three such books were so treated in 1943: the splendid book *The Embryological Treatises of Hieronymus Fabricius*, translated and edited by Howard B. Adelman, of Cornell; F. C. Irving's *Safe Deliverance*, a sound history of the Boston Lying-in Hospital and the growth of obstetrics in Boston; and Nurse Redmond's *I Served on Bataan*, a stirring account of her experiences.

SPECIAL ACCESSIONS

With book funds limited to specific purposes, the addition of books in certain fields of medicine continues to be one of the main functions of the Library. To spend such funds wisely and well is not by any means an easy task, but paths well laid down by our predecessors are usually followed in the fields of incunabula, early English imprints, Americana and books in Hebrew.

Incunabula

Twelve incunabula were added in 1943, ten after the *Catalogue* was compiled. Thus the total number of incunabula of medical and scientific interest in the Library at the end of 1943 was six hundred and eighty-four, representing the most complete collection of its type in America. With the publication of Mr. Ballard's *Catalogue*, dated 1944 but not including all accessions in 1943, it is presumed that the collection will become more widely known by scholars and consequently more useful to them. The additions, moreover, in 1943 have helped to fill out certain sections of the collection, thus carrying out our aim to make the incunabula on our shelves as representative as possible, without duplicating other holdings in Boston and its immediate vicinity. Along this line it may be noted that the addition of *De urinis et pulsibus* by Aegidius Corboliensis, according to the Stillwell *Census*, brings the first

copy of this book to New England. Three more books, or editions, of the prolific writer Philippus Beroaldus bring our total of volumes by this author up to eighteen. The Library has added another example of the *Lunarium* of Bernardus de Granollachs and now possesses three editions of this rare book: two in Latin and one in Italian. The *De lamiis et phitonibus mulieribus* by Molitoris is another book not previously listed as in New England. Still in line with the same policy is the acquisition of the *Expositio in libros posteriorum* by Thomas de Aquino, for by consulting Stillwell we find three other copies distributed in the United States, in San Marino, California, Chicago and Baltimore. With the addition of one in Boston, the regional distribution for scholars appears to be excellent. Finally, a book by Trithemius not previously represented in our collection is the only copy, according to Stillwell, in a library on the East Coast. Thus, in buying incunabula in 1943, the geographical availability of these rare books has been given due consideration in its proper relation to all the other factors that go into wise selection.

Mr. Ballard's *A Catalogue of the Medieval and Renaissance Manuscripts and Incunabula in the Boston Medical Library*, finished by February, 1943, could not be printed until the last of the year owing to war conditions, and therefore was not published until 1944. In spite of the complicated nature of the task of compiling this book, only one important error has been noted. The illustration of a manuscript in Hebrew by Bernard of Gordon (Fig. 3, page 11) was inadvertently printed upside down. This annoying oversight is not fully accounted for, but one fact in explanation, although not excusing our carelessness, is of interest. The manuscript, formerly in the Prince Dietrichstein library, was also inserted upside down by the original binder of the volume, apparently unnoticed by the Prince's librarian! A new plate, with the illustration in correct position, has been printed and distributed to subscribers of the *Catalogue* and inserted in copies for future sale.

English Imprints before 1640

Two valuable and important imprints in this class were added in 1943: the first English surgery, *The Noble Experience of the Vertuous Handy Worke of Surgery*, by Hieronymus Brunschwig, printed in Southwarke by Peter Treveris in 1525, and *The Grete Herball*, issued the next year by the same printer from the same section of London. These two books, with two others previously acquired, *The Vertuose Boke of Distyllacyon* and *The Judycyall of Uryns*, bring to the Library examples of the four important folio publications of medical interest issued in the early sixteenth century in English. They serve to illustrate the character of early Tudor medicine at a time when medieval medicine was still holding sway though beginning

to loosen its grip before the overwhelming might of the humanistic and scientific Renaissance.

Brunschwig, an Alsatian field surgeon, who wrote a detailed account of gunshot wounds, was the author of a famous work on surgery, written in the Strassburg dialect and published in Strassburg in 1497.

lieve that he was a scholarly observer who drew many valid conclusions from his practical surgery on the field of battle. The striking illustration on the title page of the man being trephined for a head wound shows marked powers of observation. The right facial paralysis is well shown; it is clearly of

FIGURE 1. The Title-Page of Brunschwig's *Surgeri* (London in Southwarke, 1525).

The book was popular and full of striking illustrations. The English translation of Brunschwig's *Surgeri* (Fig. 1), printed in 1525, omits much of the text and many of the woodcuts, but still preserves the essence of the work with the description of ligature of vessels and reduction and immobilization of fractures. Although Jerome of Brunswick has not been awarded a high place in medical history, a careful reading of this book leads one to be-

lieve that he was a scholarly observer who drew many valid conclusions from his practical surgery on the field of battle. The striking illustration on the title page of the man being trephined for a head wound shows marked powers of observation. The right facial paralysis is well shown; it is clearly of the peripheral type, with the wide palpebral fissure and smooth brow. A third nerve palsy is shown on the other side, the eye being pulled to the outer corner by the unopposed action of the sixth nerve, with the dilated pupil, the result of unrestrained sympathetic stimulation. A paralysis of the left side of the tongue is also well shown. This drawing resulted from more than a hasty glance by the surgeon. The book, moreover, contains much good

advice to students and young surgeons and was certainly worthy of the folio volume provided by Treveris. One only wishes that the whole of the book with all the illustrations had been included in the first important surgery to appear in England.

The second book, *The Grete Herball* (Fig. 2), was translated from the French by Peter Treveris, the

by Treveris became the most famous of the early English herbals. It was preceded in England by only one other herbal, issued by Richard Banckes in 1525, recently published in facsimile from the rare copy in the British Museum. ¹

An important part of herbal medicine was the preparation of the herbs by distillation. To Hierony-

FIGURE 2. *The Title-Page of The Grete Herball* (London in Southwarke, 1526).

printer of Brunswig's *Surgeri*, and issued from his press in Southwarke in 1526. Its predecessor, *Le grant herbier*, was one of the many fifteenth-century French herbals, dealing with medicinal plants and the virtues of herbs as remedies used in the treatment of disease. This was one of the most popular of the early herbals, compiled from sources going back into the Middle Ages. The book printed

mus Brunswig, the surgeon, we also turn for the most complete treatise of the time. This, *The Vertuose Boke of Distyllacyon* (Fig. 3), was published by Laurens Andrewe in London in 1527. It describes the elaborate apparatus used in the technical procedure of preparing herbs.

The fourth book deals with a study of urine, one of the most valuable aids to diagnosis known to the

sixteenth-century physician. Urinalysis was developed to such an extent that often the physician made the diagnosis without ever seeing the patient. The book was also to be used by the patient so that he could properly describe the urine to his physician.

America (Boston, 1749–1751), in two volumes, by William Douglass, the writer of the controversial pamphlets against Zabdiel Boylston, has long been a desired item. Benjamin Rush's *An Account of the Sugar Maple-tree* (Philadelphia, 1792) is a wel-

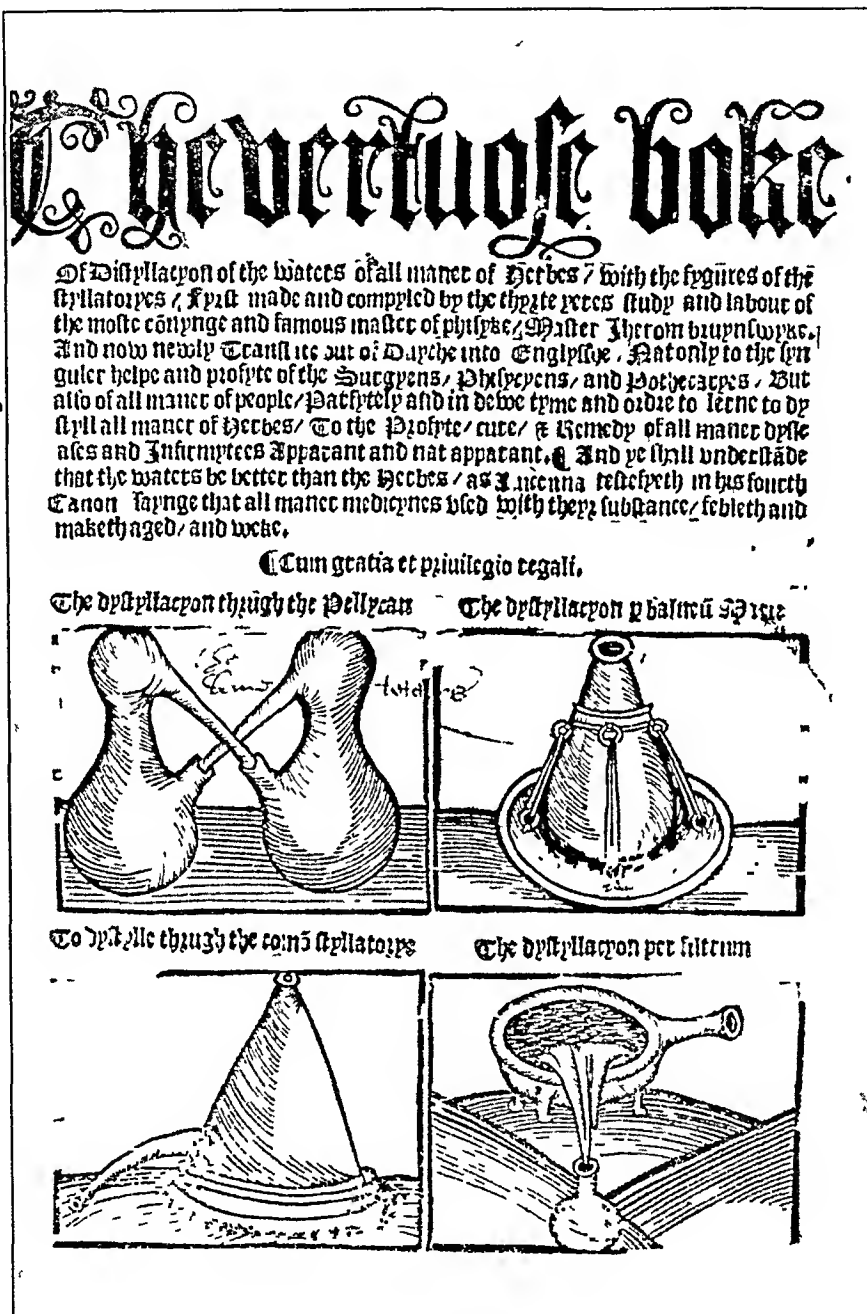

FIGURE 3. The Title-Page of Brunshaw's *The Vertuose Boke of Distyllacyon* (London, 1527).

The folio, *The Judycyall of Uryns* (Fig. 4), was published by Peter Treveris about 1527.

American Imprints

To the books published in this country we have added a few important items. The first edition of *A Summary, Historical and Political, of the First Planting . . . of the British Settlements in North*

come addition, as is the personal copy, with corrections, of *The Young Stethoscopist* (New York, 1848) by Henry I. Bowditch. The Library, moreover, has also acquired the first issue of the *Art Anatomy* of William Rimmer, published in Boston in 1877.

Other Accessions

The Library added in 1943 the daybooks of Silas Brown, of North Wilmington (1809–1844), the

prescription books from Lemon Drug Store, Marblehead (1830-1870); a considerable collection of various foreign imprints, including Linacre's translation of Galen's *De pulsuum usu*, many medical dissertations from the College of Physicians, Phila-

quarterd in our building. In addition, a rearrangement of space has allowed for a further expansion of the ever-increasing activities of the Massachusetts Medical Society, long a close associate and ardent supporter of the Boston Medical Library. With

FIGURE 4. The Title-Page of *The Judycyall of Uryns* (London, 1527?).

delphia, and the University of Rochester; and numerous other gifts or purchases.

* * *

The Library continues to enjoy its close association with *The New England Journal of Medicine* and *The Journal of Bone and Joint Surgery*, both

these friends and others, together with the loyal work of the trustees and the various committees, the librarian looks back on 1943 as a successful year in medical library history and toward a fuller stage of usefulness to the medical profession and to the public in the years to come.

HENRY R. VIETS, Librarian

tions in susceptibility to this solvent dependent on age. In his series, 277 employees were studied — 158 men and 119 women. Under the conditions of exposure to tetrachloroethane experienced by this group, striking hepatic involvement was noted, and enlargement of the liver was found in nearly 25 per cent of the women but in only 12.6 per cent of the men. Not only was there a great difference in susceptibility based on sex, but it also appeared evident that older persons were much more liable to hepatic damage than younger ones. Of workers under the age of thirty, 9.8 per cent had demonstrable liver enlargement; of those between the ages of thirty-one and fifty, 29.4 per cent showed a similar finding; and in those from fifty-one to seventy years, essentially the same percentage was involved (28.5 per cent). It seems obvious, therefore, that employees exposed to tetrachloroethane should be chosen from young men. Frequent physical examinations are desirable, with particular attention to the size of the liver. Simple laboratory procedures also are indicated at periodic intervals, and determination of the level of the bile pigments in the blood and urine has diagnostic and prognostic value. In some cases in this series, hyperbilirubinemia or the appearance of bile in the urine was the first indication of liver damage. The cephalin flocculation test seemed to give additional valuable evidence.

In view of the widespread use of carbon tetrachloride in industry as well as therapeutically, a case report of acute poisoning following the accidental ingestion of between 30 and 40 cc. of this substance is of interest. Beattie and his collaborators⁶ successfully treated such a case, which was unusual because of the large quantity of carbon tetrachloride ingested and because of the successful outcome. The maximum therapeutic dose is 4 cc., and there seemed to be no doubt that the massive dose noted above was ingested and absorbed. Within nineteen hours the liver was easily palpable. Shortly afterward intensive therapy was started, consisting of the intravenous injection of a casein digest-methionine solution, at the rate of 2 cc. a minute. At the end of three hours the infusion was stopped because of chilliness, malaise and muscle aches, and it was noted that the liver was still enlarged and tender, its edge being at the level of the umbilicus. On the following day the liver was no longer tender, and its edge had receded to within 2 cm. of the costal margin. It subsequently became enlarged again, at which time the patient was treated by the oral administration of 2 gm. of methionine in the morning and evening. On the fourth day the patient was asymptomatic, and abdominal palpation revealed a second reduction in the size of the liver to near the costal margin. The subsequent course of events was entirely satisfactory. The use of *D*-methionine in large doses in this case is of interest, and it is possible that the successful

results of treatment were primarily due to the protective effect of this amino acid.

It has long been known that many of the anesthetics commonly employed may result in transient or at times in permanent liver damage. Morrison⁷ studied the effects on liver function of seven currently used anesthetics as measured by the concentration of bile salt in the urine. Although the method employed is probably not too acceptable a measure of hepatic function, there can be little doubt that the evidence obtained by this author is reasonably accurate and suggestive. Evipal sodium, cyclopropane and nitrous oxide, under the conditions employed, showed no deleterious effect on liver function as determined by this test. Avertin and chloroform produced evidence of hepatic dysfunction lasting for twenty-four hours. Ether produced a marked disturbance in hepatic function as judged by the concentration of bile salt in surgical-drainage bile, whereas spinal anesthesia resulted in only moderate increases in elimination of bile salt. The conclusions reached in this study are in no sense new, but they are timely because of the many innovations in anesthesia that are employed at present. The chief importance of such findings should be to increase the general awareness of surgeons and anesthesiologists of the risks that may be run incident to the various types of surgical anesthesia, particularly in patients with potential hepatic damage. Because of the advantages accruing to the use of chloroform in war, it is necessary periodically to stress also its dangers. Avertin should be used with extreme caution in depleted patients and in those with biliary-tract disease, and as has been pointed out on numerous occasions, the use of ether as an anesthetic in jaundiced patients should be associated with great care and with special precautions to prevent anoxia.

The troublesome question of liver damage following the use of arsenicals has been revived because of the large number of patients receiving antisyphilitic treatment in the armed services. The hepatic pathology associated with arsenotherapy has been carefully studied by various observers. In the past, the jaundice has usually been ascribed to injury of the liver parenchyma, and in cases terminating fatally it has been possible to confirm the hepatogenic character of the jaundice by histologic studies that showed marked degenerative changes in the hepatic lobule. Hanger and Gutman⁸ in 1940 presented evidence based on liver biopsies that in some cases the icterus was the result of obstructive processes within the bile ducts rather than of injury to the liver parenchyma. In 12 cases of post-arsphenamine jaundice there was a preservation of essentially normal hepatic parenchyma, the principal lesion being pericholangitis, with bile thrombi in the finer biliary radicals. In these cases, various laboratory tests indicated little damage to

obstruction. Although the jaundice persisted for weeks or months, recovery eventually occurred. More recently Dible and McMichael,⁹ using the technic of Roholm and Iversen for obtaining biopsy material, studied 35 cases of arsenical jaundice, and in addition, cases of ordinary infectious hepatitis that were regarded as controls. These authors believed that the histologic picture and the sequence of pathologic developments in arsenical jaundice showed no significant differences from those seen in epidemic hepatitis or in the hepatitis seen after serum injections. The histologic appearance of the biopsy specimens did not support the suggestion that either syphilitic lesions of the liver or arsenobenzol poisoning played any part in their production. Although varying degrees of damage were noted, the histologic changes primarily suggested damage of the parenchymal cells.

Riddell and Anderson,¹⁰ using the oral hippuric acid test for liver function, studied a group of 188 patients already under arsenical treatment for early syphilis. Treatment consisted in the employment of neoarsphenamine or Mapharside. These authors attempted to determine whether impairment of the detoxicating function of the liver is directly proportional to the quantity of the arsenical used; whether failure of the detoxicating mechanism precedes the onset of clinical jaundice and the appearance of bile products in the urine by an interval sufficient to allow the clinician to modify the treatment; and whether the hippuric acid test is of prognostic value in postarsenical jaundice. Twenty-seven per cent of the patients receiving arsenical treatment for early syphilis excreted less than the normal amount of hippuric acid in the urine, although they were free from abnormal signs and symptoms, a finding that led the authors to believe that arsenotherapy impairs the normal detoxicating function. On the other hand, they found no direct relation between the results of the hippuric acid test of liver function and the amounts of arsenicals taken. The effect of the arsenicals on the liver, therefore, was thought to be dependent primarily on individual sensitiveness rather than on the quantity given. By means of numerous tests performed during treatment, it was shown that the failure of the detoxicating function detected in this study preceded the onset of jaundice and the appearance of bile products in the urine. Although arsenotherapy was stopped as soon as evidence was obtained of hepatic dysfunction, jaundice resulted in about one third of these cases. Tests performed every two weeks after the development of jaundice showed a steady and sometimes rapid return to normal function. A very low hippuric acid output did not necessarily imply a fatal outcome or irreparable damage to the hepatic detoxifying mechanism, a finding that should occasion little surprise.

In this regard it is of interest to refer to an article by Messinger and Hawkins¹¹ published in 1940 on

modification of arsphenamine liver injury in dogs by dietary measures. Liver injury was trivial when the animals were on a protein diet, and the damage was promptly repaired. A high-carbohydrate intake, although also beneficial, was not so highly protective as the protein diet, and on it the liver injury was sometimes somewhat greater. Progressive jaundice, severe liver injury and fatal intoxication were noted when the animals were kept on high-fat diets during the administration of arsphenamine. An interesting point, which I have confirmed in human beings, was that animals protected by high-protein or high-carbohydrate diets showed a progressive increase in the icteric index when an increase in dietary fat was given, even though no additional arsphenamine was injected. Conversely, dogs on fat-free diets that showed severe intoxication due to arsphenamine injury usually improved immediately when a shift was made to a high-protein and high-carbohydrate diet. These experimental facts are in keeping with many other investigations and are fairly well recognized, but are of special significance in relation to the care of patients who are receiving arsenotherapy for syphilis.

Of the various antisyphilitic arsenicals, Mapharsen seems to be tolerated the best. The studies of Anwyl-Davies¹² provide an interesting comparison between the results obtained after the use of neoarsphenamine and those noted following treatment with Mapharsen. Of 1946 patients treated with neoarsphenamine, the astounding number of 574 (29 per cent) developed jaundice. Of 1147 patients treated with Mapharsen, 146 (12.8 per cent) developed jaundice. Thus the latter drug not only produced less frequent evidence of hepatic damage but was also accompanied by jaundice of much shorter duration than that occasioned by other compounds, and the mortality rate was reduced. Some patients who became jaundiced after the use of neoarsphenamine tolerated Mapharsen without incident.

The possible association of infectious hepatitis (catarrhal jaundice) with arsenical jaundice has always been a moot point. For this reason the report by Mitchell¹³ is of interest. From July, 1941, to June, 1942, all soldiers in the Canadian Army in England who exhibited jaundice were hospitalized. Mitchell made a careful study of this group. A considerable number of them were found to be receiving arsenical treatment for syphilis. The clinical severity of the hepatitis encountered was relatively mild. There were no differential features between hepatitis occurring during antisyphilitic treatment and that noted in nonsyphilitic patients not receiving arsenotherapy. As suggested previously, liver biopsies showed a marked similarity of the lesions in the two groups. During the year, 0.16 per cent of the total army personnel were hospitalized for jaundice, exclusive of those suffering from extrahepatic biliary obstruction from various causes. Of these men, 17.8 per cent were syphilitic patients

receiving treatment. The remainder were nonsyphilitic patients and presumably suffered from uncomplicated infectious hepatitis. The former group represented 5.84 per cent of all syphilitic patients receiving arsenotherapy during the period. The incidence of clinical jaundice in those patients receiving arsenotherapy for syphilis was over thirty-six times as high as that in the group of syphilitic patients not receiving arsenicals. Jaundice was noted three times as frequently in the patients treated with neoarsphenamine as in those treated with Mapharsen. Deaths from acute yellow atrophy in the treated group numbered 1.47 per cent and in the untreated group 0.95 per cent. During the period reviewed, hepatitis was endemic not only in the Canadian Army in England but also in the civilian population with whom the soldiers mingled. The author suggests that a larger number of cases with infectious hepatitis without jaundice occur than has been hitherto recognized, and that it is the association of two hepatotoxic agents (arsenic and the agent of infectious hepatitis) that produces a higher incidence of infectious hepatitis in patients under arsenotherapy.

In view of recent findings in so-called "post-vaccinal jaundice," the article by Bigger¹⁴ is of interest. This author investigated the possibility that jaundice in syphilitic patients receiving intravenous arsenicals is due to the transmission of a virus from patient to patient. In the clinic under observation it was noted that the same syringe was fitted with a succession of sterile needles and was used for ten or more consecutive treatments. After each injection the syringe was thoroughly washed with sterile water and a 1:1000 solution of biniodide, five washings in all. It had been presumed that the procedure used would remove the few drops of blood drawn into the syringe at the beginning of each injection, but experiments showed that the method of cleaning the syringes was not sufficient to remove all the living organisms from it when these were present in the blood. A virus might thus pass from patient to patient in clinics where the same or similar techniques were used. Such a finding is extremely suggestive as helping to explain, at least in part, the incidence of jaundice in this particular group of patients. The suggestion of the author that a thoroughly boiled syringe be used for each patient is obviously sound.

Rossling¹⁵ studied the effect of arsenic on the liver in relation to acute and chronic forms of damage. From a variety of observations, he concluded that cirrhosis of the Laennec type due to arsenical poisoning alone is unlikely, and stresses the importance of considering the additive effects of such substances as alcohol, lead, nicotine and copper and those of infections, metabolic disturbances and cachexia. Certainly the combination of hepatic infection and malnutrition may well form the background for specific toxic damage to the

liver when the dosage of the poison is minimal. The summation effect of several factors in producing liver damage is also mentioned by Kulchár and Reynolds¹⁶ in a discussion of bismuth hepatitis. Although it can hardly be stated that liver damage from bismuth is a generally accepted fact, the survey of 120 cases made by these authors is of considerable interest. Jaundice developed in this group of patients during courses of bismuth therapy for syphilis. Except for 2 patients, all were in the latent stage of the disease. Half the entire group had received varying amounts of treatment prior to entry, but none of these patients gave a history of previous jaundice. In over 8 per cent of the patients treated, there was a recurrence of hepatitis with a resumption of bismuth therapy. The effect of previous arsenical therapy, as well as the less evident factors of diet, alcohol and intercurrent infection, was thought to have predisposed the liver to damage from bismuth.

Reports on hepatic damage following sulfonamide therapy have been occasionally presented. In most, if not all, cases such damage has appeared to be the result of an individual hypersensitivity or an organ hypersensitivity rather than of overdosage. The observations of Machella and Higgins¹⁷ are striking and worthy of comment. These authors carried out four separate experiments devised to determine the effect of sulfanilamide on the already damaged liver or on the liver predisposed to damage by a recognized procedure. The drug was administered to rats in which hepatitis had been induced by carbon tetrachloride, to a second group in which hepatitis was being induced by the same means, to a third group receiving alcohol and finally to a group in which obstructive jaundice had been induced by ligation of the common duct. In the animals in which hepatitis had already been produced by carbon tetrachloride, sulfanilamide did not increase the damage to the liver but appeared to lessen it; in the second group, the drug did not impede regeneration of the liver after the administration of carbon tetrachloride had been discontinued. In the animals receiving alcohol and sulfanilamide, no damage resulted to the hepatic cells, although in some of the animals receiving only alcohol fat was deposited in the liver. In the animals with extrahepatic biliary obstruction, no detectable injury to the liver not ascribable to the biliary obstruction was produced. On the basis of these experiments, reported in 1942, Forbes and Evans¹⁸ carried out further experiments on the protective action of sulfanilamide against hepatic damage from chloroform. These studies were made primarily because of the desirability in modern warfare of such an anesthetic, which is not inflammable and can be transported in small bulk. Acute poisoning was produced, and the animals were sacrificed twenty-four hours later. Histologic examination of the livers showed that the oral administration of

sulfanilamide apparently exerted a protective action against damage to the liver from the inhalation of chloroform in both rats and rabbits. On the basis of these experiments, the authors suggest that sulfanilamide or some other sulfonamide compound be given preoperatively to wounded men who are to be anesthetized with chloroform, and stress the wisdom of giving the drug soon enough to obtain a therapeutic level in the blood stream and liver before the administration of the anesthetic.

That sulfathiazole and sulfadiazine do not necessarily constitute a threat to hepatic efficiency in the treatment of bacterial infections is suggested by the studies of Peterson, Deutsch and Finland.¹⁹ These authors report a series of 37 patients who showed evidence of acute or chronic liver damage and who, for various reasons, received one or the other of these drugs in full therapeutic doses. Studies were made to determine the effect of the drug on hepatic function. In patients with acute hepatitis and bacterial infection, sulfonamide therapy was almost always accompanied by improvement in hepatic function paralleling improvement in the underlying infection. In patients with chronic liver damage, there was no aggravation of the hepatic condition during the administration of the drug. There was some apparent improvement in the cases in which bacterial infection was added to hepatic injury. On the other hand, severe toxic effects, other than those of direct injury to the liver, were unusually frequent in patients with portal cirrhosis and intercurrent infection. These undesirable reactions were about twice as frequent after the use of sulfathiazole as after treatment with sulfadiazine. The authors conclude that the presence of liver damage should not be construed as a contraindication to therapy with sulfathiazole or sulfadiazine in patients with bacterial infections against which these drugs are effective, sulfadiazine being the drug of choice. Caution should be exercised in the administration of sulfonamide compounds in patients with severe portal cirrhosis of the liver.

That sulfonamide therapy may occasionally result in direct damage to the liver, however, is indicated from various recent clinical reports. Menten and Andersch²⁰ report, out of approximately 300 autopsies performed during three consecutive years, 38 cases of liver disease in children who had had sulfonamide therapy. Pathologic changes included toxic necrosis of the liver in 3 patients, toxic central necrosis in 9 patients and serous hepatitis and beginning toxic central necrosis in the remainder. No relation could be established between the sulfonamide dosage and the development of liver lesions. The Gray colloidal-gold test of liver function was positive in 13 per cent of the children studied, and slightly positive in an additional 20 per cent. No correlation was found between the amount and duration of therapy and the colloidal-gold reaction. Like all recent observers,

these authors believe that inadequate nutrition may render the liver more vulnerable to the sulfonamides. They stress particularly protein depletion and an inadequate intake of vitamin B. Cantarow and Wirts²¹ mention the presence of hyperbilirubinemia following the administration of sulfonamides in an important number of cases. Twenty patients were studied, and increases of blood bilirubin were noted at periods ranging from one to seven days after the institution of sulfonamide therapy. A return to normal followed in every case after cessation of treatment. Other evidence of hepatic functional impairment was demonstrated in 2 cases treated with sulfanilamide, in 3 cases following the use of sulfathiazole, in 2 after sulfapyridine and in 3 after sulfadiazine. Hyperbilirubinemia occurred after the administration of varying amounts of the drugs and with widely varying sulfonamide concentrations in the blood. When one considers the total number of patients receiving sulfonamide therapy in one form or another without deleterious effects on hepatic function, and the paucity of cases such as those already cited, one is forced to conclude that in most cases these drugs do not cause tremendous danger to the liver, particularly when a proper indication for their employment exists. Thus, Anglem and Clute²² cite 75 cases in which intraperitoneal sulfanilamide was used following gastrointestinal resections, with a toxic reaction to the drug in only 1 case. In this case a toxic hepatitis occurred, but recovery took place.

The potential damage to the liver from the use of tannic acid in the treatment of burns has been recorded by several observers. With newer methods of treating burns, this hazard will presumably become of little or no importance. The possibility of such danger, however, should be mentioned if for no other reason than to stress the inferiority of tanning to other procedures that are less dangerous as well as more efficacious for the treatment of such common injuries. That hepatic damage may result from serious burns of large areas of the body without the addition of any chemotherapeutic factor is the assumption of Boyce.²³ This author discusses the hepatic factor in burn cases from experimental, clinical, laboratory and autopsy aspects. The article is of particular interest in relation to the unexpected fatalities that occasionally occur in slightly burned persons. It is quite possible that in these cases certain toxic factors associated with the burn exist that have produced a minimal amount of liver damage, and that additional therapeutic measures may provide the necessary factor for ultimate fatal poisoning of the liver. An autopsy report by Duffin²⁴ shows what seem to be the characteristic findings associated with tannic acid poisoning of the liver. In this case, about one twelfth of the body surface was burned, and the treatment was essentially that of tanning. Icterus developed

on the second day and progressed rapidly, with concomitant enlargement of the liver. On the eighth day, however, the jaundice had diminished and the liver was no longer palpable, but because of intercurrent pneumonia death occurred on the tenth day. An autopsy showed intense central and mid-zonal necrosis. A careful experimental study of the relation of tannic acid to liver necrosis occurring in burned patients was published in 1942 by Wells, Humphrey and Coll.²⁵ Central necrosis of the hepatic cells was noted not only in 4 patients who died following such treatment for burns but also in a large number of animals experimentally injected with tannic acid. The degree of hepatic damage in general varied directly with the amount of tannic acid injected. Further observations were made by Forbes and Evans,²⁶ who also showed that in rats tannic acid injections were hepatotoxic. These authors, moreover, found that no protection was afforded either by the oral or subcutaneous administration of sulfanilamide or by the subcutaneous administration of xanthine.

That massive burns predispose to liver damage, even in the absence of coagulating agents used in burn therapy, is indicated by the studies of Hartman and Romence.²⁷ Large experimental burns resulted in engorgement of the sinusoids of the liver, especially in the central areas. The introduction of coagulating agents — tannic acid, ferric chloride and silver nitrate — increased the incidence of degeneration and necrosis of the liver cells. Tannic acid used as a wet dressing produced clinical jaundice and central necrosis; the administration of subcutaneous tanning produced liver necrosis in 25 per cent of the animals; and when given intraperitoneally, it caused necrosis in 33 per cent. Various tannic acid preparations were employed, and similar results were obtained with each. Silver nitrate administered subcutaneously produced necrosis and edema at the site of injection and, at the same time, degeneration, hemorrhage and necrosis of the liver, but not the clinical jaundice that was observed following the use of the tannates. Ferric chloride introduced subcutaneously also produced necrosis, edema and hemorrhage at the site of inoculation, and hepatic lesions, with clinical jaundice, that resulted in death. Clark and Rossiter²⁸ obtained further information regarding the toxicity of tannic acid by following liver function in rabbits after the use of this drug. Impairment of liver function in these animals was demonstrated by intravenous galactose-tolerance tests. Barnes and Rossiter²⁹ also carried out experiments on guinea pigs and mice with tannic acid and sodium tannate that were entirely in keeping with the foregoing. After application of tannic acid to the raw area produced in guinea pigs by burns to the extent of one third of the body surface, there was slight liver damage, which was definitely greater than that seen in untreated similarly burned.

The harmful effect of other therapeutic agents on hepatic function has also attracted attention. Krupski et al.³⁰ studied the effect of caffeine on the liver in rabbits. Solutions containing several milligrams per hundred cubic centimeters did not affect the oxygen consumption of perfused rabbit livers, although higher concentrations (100 mg. per 100 cc.) increased the oxygen uptake. When the initial caffeine concentration was as high as 200 mg. per 100 cc. in the perfused blood, the final caffeine concentration after one hour or more was 17.5 per cent of the initial caffeine concentration. It is evident that the liver progressively lost the ability to destroy caffeine when the drug was administered in concentrations above 200 mg. per 100 cc.

It has been generally recognized that liver damage is accompanied by an impaired tolerance to morphine and other alkaloids. Gross³¹ carried out a study on the effect of liver damage on morphine conjugation in tolerant and nontolerant dogs maintained on a constant diet and constant water intake. Urinary morphine determinations were made before and after liver damage with the animals on a constant dose of morphine. Control observations on the damage produced by carbon tetrachloride were obtained by repeated determinations of brom-sulfalein excretion. The urine was analyzed for total, free and easily hydrolyzable morphine. The fraction of morphine that was hydrolyzable with difficulty was determined by the difference between the last two figures and the total urinary morphine. The author's earlier observation that liver damage by chloroform produced an increase in free morphine excretion also held true when carbon tetrachloride was used as the damaging agent. In addition to the marked increase in free morphine after carbon tetrachloride injury, there was a decrease in the excretion of the easily hydrolyzable fraction of combined morphine. Since the total recoverable morphine was not materially altered and the portion hydrolyzed with difficulty remained fairly constant, the easily hydrolyzable compound appeared as free morphine. One may conclude from these experiments that the easily hydrolyzable form of conjugation is the only one that takes place in the liver. Liver damage apparently inhibits the conjugation of morphine to a certain extent, as shown by the fact that the free morphine found in the urine increased without any corresponding increase in the total morphine excreted. These studies confirm and partially explain the known clinical fact that ordinary clinical doses of morphine may present special hazards when administered to patients with liver disease.

Although the exact effect of alcohol on the liver is imperfectly understood, there can be little reasonable doubt that this substance is a noxious agent in the presence of hepatic damage. It is generally accepted that the primary oxidation of alcohol in the liver. Partial removal of or

EDITH E. PARRIS, *Assistant Editor*

CASE 30251

PRESENTATION OF CASE

A fifty-six-year-old toolroom clerk was admitted to the hospital complaining of increasing weakness. The patient had been well until a year prior to admission, at which time he noted generalized weakness becoming progressively more pronounced. This was accompanied by gradual weight loss, amounting to 25 pounds. Six months before entry he had severe diarrhea, lasting about two weeks and associated on one occasion with nausea and vomiting. This was followed by a rise in temperature (105.2°F.) and a diffuse cherry-red erythema over the upper portion of the body. This episode lasted for about three days, the temperature gradually reaching normal. Following it, weakness was more pronounced, and weight loss more rapid.

Because of these symptoms he attended a local outpatient department, where he was found to have anemia (2,500,000 red cells, with 7 per cent reticulocytes). The spleen, but not the liver, was palpable. The urine showed a +++ test for albumin, with rare hyaline casts. The stomach content contained no free hydrochloric acid, and was positive for occult blood and lactic acid. Treatment with Feosol, yeast and dilute hydrochloric acid resulted in little improvement and three months later he was finally admitted to a local hospital, where he remained for five weeks. At that time the liver was palpable five fingerbreadths below the

costal margin; the spleen was still palpable. The red-cell count was 2,750,000, with 10.5 gm. of hemoglobin; the mean corpuscular volume was 109 cubic microns, the mean corpuscular hemoglobin 38 millimicrograms, and the reticulocyte count 0.4 to 2 per cent. The bleeding, clotting and prothrombin times were normal. The icteric index was within normal range. The serum protein was 8.7 gm. per 100 cc., with an albumin-globulin ratio of 2. The serum phosphatase was 13 Bodansky units per 100 cc. X-ray studies of the chest, gastrointestinal tract, long bones and pelvis were negative. A sternal marrow biopsy revealed no characteristic cellular picture, but suggested pernicious anemia. A liver biopsy revealed almost complete replacement of normal tissue cells by dense fibrous tissue in which there was bile-duct proliferation. The liver on peritoneoscopy appeared grossly enlarged and roughly granular.

Following discharge, the patient was treated with yeast and liver by mouth and parenterally, with no response, and he was finally admitted to this hospital two months later.

Physical examination revealed a pale man, showing evidence of recent weight loss. A spider angioma was present on the neck. An area of diminished resonance and inconstant inspiratory rales was present at the right base. The heart revealed a soft systolic murmur, not transmitted, over the pulmonary area. The liver edge extended from the right iliac crest to the costal margin in the left mid-clavicular line and felt somewhat nodular. The lower pole of the spleen was palpable. The prostate was slightly enlarged. There was questionable pitting edema of the ankles.

The blood pressure was 100 systolic, 60 diastolic. The temperature was 99.2°F., the pulse 80, and the respirations 20.

Examination of the blood revealed a red-cell count of 2,570,000, with 8.5 gm. of hemoglobin. The white-cell count was 5700, with 49 per cent neutrophils, 30 per cent lymphocytes, 20 per cent monocytes and 1 per cent eosinophils. There were a few macrocytic red cells. The urine revealed a +++

*On leave of absence.

test for albumin, and occasional red cells, white cells and granular casts. A bromsulfalein test showed 30 per cent dye retention. The van den Bergh was within normal limits. The protein ranged from 6.2 to 7.0 gm. per 100 cc., with an albumin-globulin ratio of 2.1 to 2.5. The blood cholesterol was 122 mg. per 100 cc., the calcium 10.7 mg., and the phosphorus 4.8 mg. The alkaline phosphatase was 4.8 units, and the acid phosphatase 1.8 units per 100 cc. A Congo red test was negative for amyloid. The prothrombin time was 22 seconds (normal, 16 seconds). A blood Hinton test was negative.

A roentgenographic examination of the chest, a gastrointestinal series and a barium enema revealed no abnormalities, except an enlarged liver and spleen.

On the sixteenth hospital day a peritoneoscopy revealed an enlarged liver, exactly as palpated, with a tongue of liver tissue extending down below the umbilicus in the right lower quadrant and flank. The surface was mottled, reddish-yellow and questionably granular; there was a fairly sharp edge. There was no evidence of neoplastic implants. The spleen was about twice its normal size, smooth and dark brown. There was no ascites. The liver was biopsied.

DIFFERENTIAL DIAGNOSIS

DR. CHESTER S. KEEFER*: The patient was fifty-six years of age and had been ill for over a year with constitutional symptoms and loss of weight, increasing fatigability and weakness. In the past there had been one episode of diarrhea of two weeks' duration, during which time he developed a temperature of 105°F., and a diffuse cherry-red erythema over the upper part of the body. I am unable to explain that episode. It has occurred to me that perhaps this man had received some sulfonamide from one of his physicians for the treatment of diarrhea and developed the fever and skin eruption as a result. It is not stated, however, in this record whether that was known. There are few patients who have diarrhea of more than two or three days' duration who do not receive one of the sulfonamides; some of them develop fever and a skin eruption if the drug is continued for a period of seven days or longer.

One might, for the sake of mental exercise, indulge in some speculations concerning what other disorders cause diarrhea and skin eruptions. We know that certain strains of hemolytic *Staphylococcus aureus* are capable of liberating exotoxin as well as endotoxin, and occasionally these patients show a typical scarlatiniform eruption associated with infection. These infections are of short duration, the skin lesions are exfoliative in charac-

ter, and the gastrointestinal symptoms appear within a short period after the ingestion of food. The common foods that are contaminated by the staphylococcus, of course, are custard pies and the filling of cream puffs. If the organisms grow freely, they liberate an exotoxin and some strains liberate an erythrogenic toxin, which is exceptionally difficult to distinguish from the streptococcal erythrogenic toxin. Antiscarlatin antiserum will, on occasion, blanch the rash of staphylococcal infection.

When this patient was admitted to the first out-patient department he had an anemia with enlargement of the spleen and albuminuria. This anemia apparently did not respond to any form of treatment that was prescribed — iron, yeast and dilute hydrochloric acid. One might expect that the anemia would be refractory to hydrochloric acid, but not to the iron or the yeast. On admission to that hospital the anemia was still present and was hyperchromic. The sternal marrow biopsy showed nothing definite but was suggestive of pernicious anemia. The liver biopsy showed dense fibrous tissue, with bile-duct proliferation. That is the picture that one might see in extensive cirrhosis of the liver. With fibrosis, the bile ducts make a frantic effort to proliferate and to join up with the new nodules in an attempt to excrete bile from these cells. I think that we cannot accept that conclusively, however, in light of the fact that the liver increased in size rather than decreased. In any event it seems clear that this anemia was refractory and did not respond to liver, and that it was not an ordinary pernicious anemia.

The physical examination on the last admission says that a spider angioma was noted over the neck. When one finds spider angiomas it is usually suggestive that the patient has liver disease. These spider angiomas attracted attention in the medical literature over twenty-five years ago. If you read about the old descriptions of cirrhosis of the liver they are freely discussed. Then, for a long time no one paid any attention to them, but in the last few years a great deal of interest has again been shown. They are dilated arterioles, and when examined carefully, they tend to occur only on the upper half of the body and, for some curious reason, over the area drained by the superior vena cava. It has been suggested that the disturbances in the estrogenic hormones that take place in liver disease may be responsible for these angiomas. In any event it was noted here that there was a spider angioma on the neck, suggesting that the man had liver disease.

Then, once again, there were enlargement of the liver and spleen, anemia that did not respond and albuminuria. Someone expressed the opinion that this man may have had amyloid disease because of the albuminuria, the big liver and the enlarged spleen. This was a good suggestion, but the Congo

*Director, Evans Memorial, Massachusetts Memorial Hospitals; physician-in-chief, Massachusetts Memorial Hospital; and Professor of Medicine, Boston University School of Medicine.

A bromsulfalein test showed

that he retained at least 30 per cent of the dye, indicating that he had a disturbance of hepatic function.

The x-ray studies were negative except that they showed an enlarged liver. Finally, there was another peritoneoscopy, and they found that the liver was still large; a biopsy was taken, and Dr. Castleman will shortly tell you the diagnosis.

The question that arises in this patient, of course, is, Was this simply a case of cirrhosis of the liver, or was there some process superimposed on the cirrhosis? If one assumes that it was just cirrhosis, it is difficult to explain why the liver was enlarged. One must believe the record, which states that the liver increased in size from the first admission until the time of the biopsy that disclosed the answer. Patients who have an enlarging liver usually have some infiltrating process in that organ. The one type of liver disease that is associated with fibrosis, and even with cirrhosis, and a very large liver is the fatty liver. They may reach enormous proportions, weighing 4000 to 5500 gm. The story in these cases is usually characteristic. The patient is either a heavy gin or whisky drinker, consuming anywhere from a pint to a quart a day over many years. There is no evidence that this was an enlarged fatty liver.

The first examination, with the tender spleen and hyperchromic anemia, certainly suggests that he might have had pernicious anemia, but that was not borne out by the therapeutic test and did not seem to be borne out by the gradual enlargement of the liver. One may encounter a refractory form of macrocytic anemia in patients with cirrhosis of the liver or some disorder of the bone marrow, such as a lymphoma. That naturally raises the question whether this patient might have had a lymphoma with a big liver, a big spleen and an anemia that was macrocytic in type. From the original biopsy, however, there is no evidence that there was lymphocytic infiltration of the liver. The bone marrow showed no changes consistent with the diagnosis of lymphoma. So we have no basis in this record for making such a diagnosis.

It seems to me that the likeliest explanation for this case is that the patient had a cirrhosis of the liver on which was superimposed a carcinoma, but when one makes that diagnosis one is always treading on dangerous ground. There are two forms of primary liver-cell cancer. One is a hepatoma, in which there is an initial lesion that expands and usually metastasizes by way of the veins, so that there is one large lesion with multiple small or varying sized nodules in the liver, with few metastases elsewhere. The other type of liver-cell carcinoma usually arises from the small bile ducts. There is some evidence in this case that diffuse fibrosis of the liver was present, with bile-duct proliferation. That is somewhat suggestive that this proliferation of the bile ducts was not just the type that one

the liver with disorganization of the tissue. The one point that I cannot explain on the basis of uncomplicated cirrhosis of the liver is the fact that the liver was so large. We know that it was fibrous and that the liver increased in size. These are the points that lead me to suspect that this man had cirrhosis of the liver with a superimposed carcinoma of the bile-duct-cell type. That is the best diagnosis that I can offer; perhaps, in addition, the patient had some degree of nephrosclerosis.

DR. BENJAMIN CASTLEMAN: The field is still wide open.

A PHYSICIAN: The patient had diarrhea for two weeks, high fever and a large spleen. The liver increased in size so rapidly, without pain or jaundice, that one might suspect that he had either amebiasis or some other infection that was causing an abscess there.

DR. CHESTER M. JONES: It seems to me that, with an amebic abscess, the patient would have been running a septic temperature.

DR. CASTLEMAN: The chart was flat.

DR. WYMAN RICHARDSON: How about the right half of the diaphragm?

DR. LAURENCE L. ROBBINS: It is normal. About all that these x-ray films do is to confirm the findings of physical examination — an enlarged liver, which extends down over the iliac crest, and a large spleen, which is visible below the costal margin. The only thing that I can add is that there are definitely no varices of the esophagus. The diaphragm is perfectly smooth in outline and shows nothing to suggest lobulation.

DR. RICHARDSON: The bone marrow was normal?

DR. CASTLEMAN: That examination was done at another hospital. We have only the report.

Dr. Jones saw this patient and said: "I am not convinced that cirrhosis is the answer, although it may be. The lack of fever, varices and ascites and the presence of a big liver make me question the diagnosis of cirrhosis of the liver." Have you any further comment, Dr. Jones?

DR. JONES: No, except I think that the first biopsy report of fibrosis and apparent bile-duct proliferation does not prove that that was the picture throughout the liver. I do not believe that it was.

DR. CASTLEMAN: Unless a man is expert at taking a biopsy through a peritoneoscope, he may take a bit of the capsule of the liver, with little underlying tissue, so that the specimen is not a true sample of the liver.

DR. JONES: The specimen may be a thickened capsule with a few bile ducts, and thus does not give an accurate picture. I do not believe that this biopsy makes or breaks the diagnosis. If it were pure cirrhosis, it would tend to be a fatty liver, as Dr. Keefer has pointed out, or biliary cirrhosis. The description given at the second peritoneoscopy — a smooth or finely granular liver with mottled

yellow areas — is not at all unlike what we see in cases of biliary cirrhosis, but it is curious for biliary cirrhosis to show this clinical picture. It does happen, but it is unusual.

DR. CASTLEMAN: How would Dr. Keefer account for the appearance of the liver at the second peritoneoscopy with a diagnosis of cirrhosis and hepatoma? Would they not be easily visible?

DR. KEEFER: That would depend entirely on how far from the surface the hepatoma was. In some hepatomas the original mass is beneath the capsule and does not project beyond the capsule. Although many of them produce large lobulated masses of the liver, a few do not.

DR. RICHARDSON: It would be useful to have detailed information regarding the blood picture. This

CLINICAL DIAGNOSIS

Cirrhosis?
Carcinoma of liver?

DR. KEEFER'S DIAGNOSIS

Cirrhosis of liver, with superimposed bile-duct-cell carcinoma.

ANATOMICAL DIAGNOSIS

Plasma-cell myeloma involving liver and bone marrow

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The biopsy of the liver showed no evidence of cirrhosis. The most striking finding

FIGURE 1. Photomicrograph of the Biopsy Specimen from the Liver.

was a macrocytic anemia. Pernicious anemia could account for it.

DR. CASTLEMAN: I do not believe that the blood picture as reported gave evidence of pernicious anemia.

DR. RICHARDSON: The mean cell volume was 109 cubic microns. I do not know where it was done. If it was done in the Baker Memorial Laboratory that would be on the macrocytic side. Ordinarily it should perhaps be more than that before one could be sure that it was really a macrocytic anemia; 120 cubic microns would be quite suggestive, 109, slightly suggestive.

DR. J. H. MEANS: I suppose it could be lymphoma, although there is no proof of it. He had a large spleen, anemia and fever on one occasion, all of which is suggestive.

was tremendous dilatation of the sinusoids, which were filled with typical plasma cells (Fig. 1). This patient, therefore, had plasma-cell myeloma involving the liver.

To confirm that diagnosis a sternal biopsy was done, and this showed that the marrow was almost completely replaced by plasma cells. When that was confirmed a peripheral blood smear was examined by Dr. Richardson, who found plenty of plasma cells.

The urine was examined and found to contain Bence-Jones protein, which had not been looked for before.

The patient died at home three months later, but no post-mortem examination was performed.

X-ray films were taken after the diagnosis was established.

count was 2,180,000, with 8.3 gm. of hemoglobin. The blood nonprotein nitrogen was 36 mg. and later 26 mg. per 100 cc., and the chloride 88.5 milliequiv. per liter. The blood protein varied from 5.8 to 7.2 gm. per 100 cc., with an albumin-globulin ratio of 0.8. A formol-gel reaction was positive (+ after five minutes, ++ after two hours and +++ after twenty-four hours). A brom-sulfalein test revealed 10 per cent of dye in the serum after twenty-four hours. The urine urobilinogen was normal. A chest film on the eleventh postoperative day was normal.

The patient received two transfusions and numerous intravenous infusions but continued to become weaker. He finally became comatose; the temperature fell to 93.8°F., breathing became very slow, and he finally expired on the twenty-seventh postoperative day.

DIFFERENTIAL DIAGNOSIS

DR. CHESTER M. JONES: It is apparent from the first few paragraphs of the history that this patient had symptoms of ulcer, proved by x-ray and subsequently by operation. The only discrepancy is the x-ray examination, which implies that the ulcer was in the prepyloric region, but it actually turned out to be at the pylorus, where the incidence of malignant disease is much lower. He had diabetes on the first admission with a high blood sugar and glycosuria. Then there is the statement, which I am not willing to take at face value, that he had had cirrhosis. It is an interesting statement, and I wonder if it is true.

DR. BENJAMIN CASTLEMAN: Dr. Harwood, do you know whether this patient had had cirrhosis in the past?

DR. REED HARWOOD: His employer stated that the patient had vomited blood and that a diagnosis of cirrhosis had been made, but I think it would be fair for this discussion to say that at the first operation hepatic changes were not seen.

DR. JONES: I do not believe that there is any reason to say he had cirrhosis on the basis of the story or the findings. Everything is against it, and the hematemesis was probably due to ulcer rather than to esophageal varices. Against the diagnosis of cirrhosis at the time of the first admission are the facts that no liver or spleen was felt, that no x-rays were taken to demonstrate esophageal varices and that he had a dye retention at the end of thirty minutes of only 5 per cent or less. The diagnosis ought to be put in a pigeonhole as a very improbable background against which the rest of this picture is laid. Another variable is the hypertension on admission (systolic 210, diastolic 110), which subsequently disappeared. On the first admission one would be entitled to say that he had hypertension and hypertensive heart changes.

I know nothing about the operative findings. It would be interesting to know about the liver, the

gall bladder and the pancreas. In doing a subtotal resection the surgeon should have learned a good deal about these organs. I do not suppose, however, that it is possible to get this information at the moment.

DR. CASTLEMAN: It is not in the operative note.

DR. JONES: It should have been, but after a difficult operation, where the surgeon's main attention is directed toward a difficult diagnostic problem, the omission can be understood. The operative note should be as full as possible, and in my experience operations with detailed surgical notes are of immense value afterward.

DR. CASTLEMAN: The duodenum in the region of the ulcer was adherent to the pancreas, and no attempt was made to free it.

DR. JONES: The chances are that the patient did not have gross cirrhosis of the liver or cancer of the pancreas, since the surgeon would have noticed it. This patient had a striking loss of weight during the few months before the first admission, a drop from 155 to 123 pounds in a month. That could have been due to diabetes, and yet it does not seem that the diabetes was quite that severe. Possibly there was some associated disease which at that point had not come to light.

The next series of events came after the operation. He went home for three and a half months, and the diabetes, which may have caused the marked loss of weight and certainly caused increased thirst and polyuria, disappeared from the picture. He had no diabetic symptoms and was having insulin reactions on relatively small doses of insulin. He may have had only a mild diabetes. His appetite was poor after operation, and he had gaseous eructations after meals. After subtotal gastrectomies the majority of patients do extremely well, eat three good-sized meals without symptoms and gain weight rapidly. A fair number, on the other hand, do not have a good appetite and are unable to eat adequately without discomfort, even though their ulcer is cured. Then there is an intermediate group with a long convalescence and slow gain in weight. Three weeks before re-entry he became jaundiced and something new came into the picture that had not been found on careful physical examination three and a half months earlier—a mass that his physician thought was gall bladder. The liver was slightly enlarged and tender, and in addition, a lobular mass was found in the region where the gall bladder could and frequently does lie—the mid-clavicular line under the hepatic border.

The blood pressure, which had been 210 systolic, 110 diastolic, was 110 systolic, 70 diastolic. That is a rather striking single fact. I cannot explain it, unless it was associated with general loss of weight and of appetite and loss of body tone. It is a curious change.

On readmission we have further evidence that the diabetes was either nonexistent or extremely mild,

DR. IRWOOD: When I first saw this patient he came in for study because of abdominal pain and diabetes. He had severe diabetes, and my recollection prior to preoperatively he needed 60 units of insulin. He had never been sugar free before the gastric resection, but immediately following operation his diabetes diminished, and he was discharged on 24 units of protamine insulin. I followed him for the next three months, and he did well on a four-stage gastric diet and had no digestive symptoms. He continued to feel poorly, however, and was never able to do the lightest type of domestic work. He was still weak, and I could not understand why. His blood pressure was 95 systolic, 60 diastolic. I kept wondering if the combination of decrease in need for insulin and of drop in blood pressure was due to adrenal-gland deficiency and kept watching for signs of pigmentation that never developed. He returned to the hospital, but unfortunately we did not get a blood sodium. His jaundice developed at the same time that he began to have gaseous eructations and loss of appetite, and as I remember, there was no pain associated with it.

DR. LELAND S. MCKITTRICK: I have arrived just in time to explore the patient, I take it.

DR. JONES: Yes, and may I ask a question? I made the statement, which I should like to have you comment on, that ordinarily one would have done more than a cholecystostomy for obstructive jaundice, and therefore the explanation is that the patient was too sick to do more or that a condition was found at operation that made it unwise to go farther. Is that reasonable?

DR. MCKITTRICK: Or else that I did not want to burn any bridges.

We were told that he had had cirrhosis over a long period of time. In addition, he had a big palpable gall bladder and he really had an enormously dilated biliary tree, so that, regardless of cirrhosis or anything else, he must have had obstruction of the outlet to the common duct. What it was, or what was back of it all, we knew no more at the completion of the operation than we did at the beginning. The patient was a sick man and was getting sicker, and one of the reasons he was getting sicker was the biliary obstruction. Therefore the obvious thing to do was to relieve the biliary obstruction and do no more, and that is where he was left.

DR. JONES: I am sorry that you were not here to hear a statement that I made. If he had cirrhosis, unless it was a slight biliary cirrhosis, would it not have been easily noticed at the first operation?

DR. MCKITTRICK: When one is presented with a big problem, and one as important as this, it is surprising how blind one may be.

DR. JONES: I suggested that.

DR. MCKITTRICK: It is possible that he had cirrhosis of the liver.

My general concern was eliminating what at that time was thought to be carcinoma of the stomach.

The only type he could have had would have been a moderate biliary cirrhosis without jaundice or evidence of biliary obstruction.

CLINICAL DIAGNOSES

Carcinoma of head of pancreas?
Biliary cirrhosis of liver.
Diabetes mellitus.

DR. JONES'S DIAGNOSES

Extrahepatic biliary obstruction, due to malignant disease (probably cancer of ampulla of Vater or of pancreas).
Moderate hepatic changes secondary to biliary obstruction.

ANATOMICAL DIAGNOSES

Carcinoma of head of pancreas.
Biliary obstructive cirrhosis, very early.
Bile nephrosis.
Diabetes mellitus.
Hyalinization of islets of Langerhans.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The autopsy on this man showed a finely granular greenish liver that was not particularly big; we thought at that time that it was an obstructive type of lesion—general bile stasis or perhaps a mild obstructive cirrhosis.

DR. JONES: Of six or eight weeks' duration?

DR. CASTLEMAN: It could have been longer.

The head of the pancreas was firm, and on sectioning it contained areas of yellowish necrosis, which we were not too sure were carcinoma. Most of us thought that they probably were, but there were no firm granular areas such as one usually sees in carcinoma of the head of the pancreas. The microscopic sections, however, showed that it was a primary cancer of the head of the pancreas.

He also had a mild bile nephrosis and an extremely early biliary obstructive cirrhosis.

DR. HARWOOD: Possibly the thing that cured the diabetes was anorexia and the resultant starvation, which used to be the antidiabetic treatment before insulin was discovered.

DR. CASTLEMAN: The pancreas showed marked hyalinization in the islands of Langerhans, which we have seen in about half our diabetic cases.

DR. HARWOOD: Were the adrenal glands normal?

DR. CASTLEMAN: Yes.

BACILLARY DYSENTERY IN THE UNITED STATES

It is generally believed that dysentery is a disease primarily encountered in tropical and subtropical regions. As a matter of fact, epidemic and endemic bacillary dysentery occurs throughout the world, and although less of a public-health problem in the temperate than in the tropical zones, should be constantly kept in mind by all practicing physicians. The subject has recently been reviewed by Weil,¹ and several of its aspects deserve comment.

Bacillary dysentery is caused by a variety of organisms, including *Bacterium shigae*, *B. flexneri* (including a variant, the Newcastle strain), *B. sonnei* and *B. ambiguum* (Schmitz bacillus). Fortu-

nately, the organism causing the most serious type of dysentery, *B. shigae*, is practically unknown in the United States, the etiologic agents in order of frequency being *B. flexneri*, *B. sonnei* and the Newcastle bacillus. The last is more or less limited to the southern states.

Epidemics of dysentery are chiefly confined to institutions or hospitals for the care of patients with mental diseases or of children—in other words, where living quarters are crowded, where faulty habits of personal hygiene frequently exist and where the carrier rates are usually high. On the other hand, the disease occurs endemically throughout the United States. This is evidenced by the fact that in 1933–1937 vital statistics from twenty-one states recorded over 79,000 cases, with a mortality of 17.8 per cent, and since the actual death rate is believed to be about 2 per cent, this means that the total number of cases, reported and unreported, was in the neighborhood of 700,000. The fatal cases occur chiefly in infants and children; in fact, prior to 1910, diarrhea and enteritis were the most frequent cause of death in infants. Although these diseases have subsequently shown a remarkable decline in many sections of the United States, they are still only exceeded by prematurity as a cause of infant deaths in many southern states.

Infection is spread by direct contact with patients or healthy carriers and by food contaminated by such persons or by flies in areas where there are improper facilities for sewage disposal. The importance of the carrier problem is evidenced by the fact that dysentery bacilli have been cultured from 0.1 per cent of healthy persons in institutions in New York City and from 3.8 per cent in Georgia and New Mexico, from 28 per cent of healthy persons in families in which there had been a case of bacillary dysentery, and from 80 per cent of the inmates of a children's institution in which the disease had been present in epidemic form.

Control of the disease is dependent on adequate methods of sanitation and on the proper handling of patients and of carriers. The patient with bacillary dysentery harbors the causative organism in his intestinal tract for varying periods of time: nearly 3 per cent develop a chronic form of the disease, and 80 per cent of all patients yield positive

stool cultures for a month or more after the acute attack.

Of primary importance is full appreciation by the physician that the disease rarely causes the textbook picture of acute bacillary dysentery, general malaise with one or two days of slight fever, with or without loose stools, being the most frequent clinical syndrome. The patient should not be discharged until an appreciable number of negative cultures have been obtained—the British authorities recommend eight negative cultures in four weeks, or six in six weeks. Certain of the sulfonamide drugs, particularly those that are slowly absorbed from the intestinal tract, such as sulfaguanidine, have been claimed to be effective in ridding the bowel of the bacilli; in fact, a recent report states that in 208 cases, of which 190 were caused by *B. flexneri* and 18 by *B. sonnei*, that occurred among the armed forces in North Africa the stools were negative in 194 after one course of treatment with sulfaguanidine and those of the remainder became negative after a subsequent course of sulfadiazine.² Others have reported less successful results, particularly in cases due to *B. sonnei*, but this method deserves a thorough trial.

The detection of carriers presents a difficult problem. It is obvious that all carriers cannot be discovered, and even the examination of food handlers in institutions, hospitals, hotels, restaurants and the like has proved to be impractical. One of the most effective methods of lowering the incidence of the disease is the enforcement of proper personal-hygiene practices among food handlers.³

Although typhoid fever has been practically eradicated in temperate zones, it appears unlikely that the same results can be obtained with bacillary dysentery. On the other hand, there is no doubt that the incidence of the disease can be greatly lowered if proper precautions are observed.

INJURIES TO THE EYES FROM AIR RIFLES

INJURY to the eye from the pellet of an air rifle is an all too frequent injury. Probably there is no time during the year when one cannot find on the wards of one of the Boston eye hospitals a patient whose eye has been injured in this manner. Usually the pellets, although they strike the eye with great force, do not perforate the globe. The violent contusion, however, may lead to the most serious complications. One often sees massive intraocular hemorrhage, dislocation of the lens, cataract, ruptures of the retina and choroid, and detachment of the retina. Seldom does an eye injured in this way escape permanent damage, and often permanent total blindness results.

This is truly preventable blindness. So long as air rifles are allowed to come into the hands of young people these injuries are bound to occur. The world would be no loser if this gun were outlawed. Since, however, there is no control over those who are permitted to use air rifles, every Massachusetts physician should comply with the law that requires the reporting of all such injuries and should conform to the other suggestions that appear in a letter published elsewhere in this issue of the *Journal*.

MASSACHUSETTS MEDICAL SOCIETY

DEATH

DOWNING—Andrew F. Downing, M.D., of Cambridge, died June 2. He was in his sixty-seventh year.

Dr. Downing received his degree from Harvard Medical School in 1904. He was a member of the staffs of the Cambridge City Hospital, Boston Dispensary, St. Elizabeth's Hospital and the Massachusetts General Hospital. He was a member of the American Medical Association and a former president of the Cambridge Medical Improvement Society. His widow and two daughters survive.

COMMENT

Chicken pox continues at a high level. The seasonal decline is also slow this year.

Diphtheria continues at a fairly high level as compared with last year. The figure for May is exactly twice the seven-year median.

Bacillary dysentery figures are high but most of the cases occurred in a large state hospital.

This is the third successive month in which meningococcal meningitis has been lower than in the corresponding month in 1943.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from: Newton, 1; total, 1.

Diphtheria was reported from: Belmont, 1; Boston, 4; Fairhaven, 1; Fall River, 1; Haverhill, 2; Lawrence, 3; Medford, 1; Melrose, 1; Somerville, 6; West Newbury, 1; Winthrop, 1; total, 22.

Dysentery, bacillary, was reported from: Boston, 1; Chicopee, 2; East Bridgewater, 1; Newton, 1; Worcester (State Hospital), 31; total, 36.

Encephalitis, infectious, was reported from: Billerica, 1; Worcester, 1; total, 2.

Malaria was reported from: Andover, 1; Boston, 2; Brookline, 2; Cambridge, 4; Camp Edwards, 7; Concord, 1; Cushing General Hospital, 9; Fort Banks, 10; Fort Devens, 19; Hanson, 1; Haverhill, 3; Holbrook, 2; Holyoke, 1; Medford, 5; Revere, 1; Salem, 1; Somerville, 3; U. S. Marine Hospital, Boston, 1; Wakefield, 3; Waltham, 1; Warcham, 1; Weymouth, 1; Woburn, 2; Worcester, 1; total, 82.

Meningitis, meningococcal, was reported from: Amherst, 1; Attleboro, 1; Boston, 19; Brockton, 1; Brookfield, 1; Cambridge, 2; Chelsea, 1; Easton, 1; Everett, 1; Fall River, 1; Fitchburg, 1; Hingham, 1; Lawrence, 2; Lexington, 2; Lowell, 1; Malden, 1; Millville, 1; Needham, 1; Newton, 1; North Attleboro, 1; Oxford, 1; Quincy, 2; Reading, 1; Salem, 1; Seekonk, 1; Somerville, 3; Springfield, 2; U. S. Marine Hospital, 1; Winthrop, 1; total, 54.

Meningitis, Pfeiffer-bacillus, was reported from: Monson, 1; total, 1.

Meningitis, pneumococcal, was reported from: Brockton, 1; Easthampton, 1; Ware, 1; total, 3.

Meningitis, streptococcal, was reported from: New Bedford, 2; total, 2.

Meningitis, other forms, was reported from: Boston, 4; Lynn, 1; total, 5.

Meningitis, undetermined, was reported from: Hingham, 2; Needham, 1; New Bedford, 1; Quincy, 1; Southbridge, 1; Springfield, 1; Weymouth, 1; Worcester, 1; total, 9.

Salmonella infections were reported from: Gardner, 1; Holden, 1; Malden, 2; Manchester, 3; Melrose, 1; Springfield, 1; Wellesley, 2; Worcester, 4; total, 15.

Septic sore throat was reported from: Boston, 10; Carver, 1; Everett, 1; Haverhill, 3; Hingham, 2; Lowell, 1; Malden, 1; Mansfield, 1; Quincy, 1; Winchester, 1; total, 22.

Trichinosis was reported from: Boston, 1; total, 1.

Typhoid fever was reported from: Attleboro, 1; Brockton, 1; Newton, 1; total, 3.

Undulant fever was reported from: Boston, 1; Bridgewater, 1; Danvers, 1; Egremont, 1; Fitchburg, 1; Great Barrington, 1; Shelburne, 1; total, 7.

CORRESPONDENCE

INJURIES TO THE EYES FROM AIR RIFLES

To the Editor: Since the start of the war there has been an alarming increase in the number of eyes seriously injured by BB guns. This is not surprising when one stops to note that children of all ages are war conscious, as evidenced by the preponderance of toys fashioned in military motives. The present law, a copy of which is appended, requires that all air-rifle injuries be reported to the Commissioner of Public Safety and to the police, regardless of the triviality of the wound.

The Massachusetts Division of the Blind is extremely anxious to get statistics on all BB-gun injuries. Its program of prevention of blindness can make no concession with the use of these dangerous toys by children, and it is exerting every effort to make illegal the sale of this weapon. Most of these injuries occur in children under sixteen years of age, and oftener than not, it is an innocent person who is the victim. The time to act is before an accident occurs. The non-magnetic character of the pellet makes for a poor prognosis in the eye, although it may do no serious damage elsewhere in the body. For the sake of many potential victims every physician in the Commonwealth is urged to:

- Comply with the law requiring that all BB-gun injuries be reported to the Commissioner of Public Safety and to the local police department.
- Drop a card to the Massachusetts Division of the Blind, 110 Tremont Street, Boston, stating that a case has been treated (regardless of what part of the body was struck).
- Spread the word of the dangers of BB guns to all patients.

ARTHUR F. SULLIVAN, *Director*
Division of the Blind

110 Tremont Street
Boston

* * *
CHAPTER 112

Section 12A. Every physician attending or treating a case of bullet wound, gunshot wound, powder burn or any other injury arising from or caused by the discharge of a gun, pistol, BB gun, or other air rifle or other firearm, or, whenever any such case is treated in a hospital, sanitarium or other institution, the manager, superintendent or other person in charge thereof, shall report such case at once to the commissioner of public safety and to the police authorities of the town where such physician, hospital, sanitarium or institution is located. . . .

DEPRIVATION OF LICENSE

To the Editor: At a meeting of the Board of Registration in Medicine held May 17, the Board voted to revoke the license to practice medicine in this Commonwealth of Dr. Louis L. Hoff, Holyoke, Massachusetts, because of gross misconduct in the practice of his profession as shown by his conviction in court.

H. QUIMBY GALLUPE, M.D., *Secretary*

PERFORATED PEPTIC ULCER*

A Follow-Up Study of One Hundred Cases

ASHBEL C. WILLIAMS, M.D.†

BOSTON

DOES operative closure of an acutely perforated ulcer result in cure of the ulcer? Is acute perforation of a peptic ulcer an indication for gastric resection? What is the prognosis, and what regime should be recommended after a patient has recovered from the immediate episode of an acute perforation? In which cases is further surgery indicated?

The ensuing study was undertaken for the purpose of gathering information that would be helpful in answering such questions as the above and that, from a broader standpoint, would contribute to the establishment of sound criteria governing the follow-up management of perforated peptic ulcer. A number of papers dealing with perforated peptic ulcer have appeared in the literature during the past twenty years, but these publications have been concerned for the most part with the diagnosis and operative treatment of the acute perforation. In the present study, these latter aspects will be only briefly mentioned, emphasis being placed on the follow-up results and ultimate prognosis.

No attempt will be made to review the literature, since a fairly complete review was published by Sallick¹ in 1936.

MATERIAL

From the record files of the Boston City Hospital a complete roster was obtained of all the patients operated on for acutely perforated peptic ulcer at that institution from 1934 to 1941, inclusive. Those patients who died during the period of postoperative hospitalization were excluded, leaving about 300 patients who survived the immediate convalescence. These patients were requested by letter to return to the Outpatient Department for follow-up studies, and 104 of them complied. For simplicity of statistics the last four patients responding were not included in this study. They did not differ significantly from the preceding 100 patients, every one of whom

was interviewed and examined by me on one or more occasions, a gastrointestinal barium study being requested in each case. Patients who replied by letter or telephone and did not report in person were also excluded. Previous to this study, the majority of the patients had returned to the Outpatient Department on several occasions for follow-up examinations or treatment. Their previous outpatient records and the inpatient records in all cases were carefully studied. Every effort was directed toward making observations both impartial and accurate.

In the present series, 27 of the patients were in the fourth and 32 in the fifth decade at the time of perforation. The incidence falls steadily as one proceeds toward the younger and older age groups. The youngest patient was nineteen years of age and the oldest seventy-four. Ninety-seven patients were males and 3 per cent were females. This unexplained preponderance of perforation in the male sex has been noted in all previous studies.

The average length of the follow-up period was three years and four months, the longest period being twelve years and the shortest six months.

The ulcer was gastric in 54 cases, — prepyloric in 42 and located elsewhere in the stomach in 12, — duodenal in 40, and pyloric in 3; in the remaining 3 cases the exact site was not stated. In all cases the ulcers were in the anterior wall of the stomach or bowel. There were no cases of multiple perforations occurring simultaneously.

SURGERY OF THE ACUTE PERFORATION

The operative treatment of the acute perforation has been the source of considerable diversity of opinion. A review of the recent literature reveals, however, that a substantial majority of surgeons regard simple suture as the procedure of choice.¹⁻⁶ Gastroenterostomy is thought to be indicated in addition to simple suture only in cases in which the ulcer is so encroached on as to make a probable complication.

*From the Third Surgical Service, Boston City Hospital, and Boston University School of Medicine.

†Formerly surgical resident, Boston City Hospital, and assistant surgeon, Boston University School of Medicine.

little justification for other procedures. It seems wisest to perform the simplest operation that will tide the patient over the emergency.

Simple suture alone was employed in 94 cases in this series. Local excision of the ulcer followed by suture of the resulting defect was performed in 2 cases. In 2 cases gastroenterostomy was performed along with simple closure of the ulcer. The ulcer was excised and pyloroplasty carried out in 1 case. Appendectomy was performed in addition to simple suture in 1 case, the original diagnosis having been acute appendicitis. It thus becomes obvious that this study is concerned almost entirely with the follow-up of patients treated by simple suture alone. The other procedures were too few to be of any statistical significance.

No effort was made to determine the operative mortality of the acute perforation among the 300-odd patients treated during the period from 1934 through 1941. However, Morrison,⁷ also working at the Boston City Hospital, in a statistical analysis of 200 cases of acutely perforated ulcer found the operative mortality to be 21 per cent. Although his study was carried out from 1930 through 1935, his figures apply in a general manner to the series of cases considered herein.

Following suture of the perforation, the average patient at the Boston City Hospital was maintained on parenteral fluids for one to four days and then started on frequent feedings of water, milk and cream, and Sippy powders. A week or ten days postoperatively a progressive convalescent Sippy diet was allowed. When discharged the patient was given printed instructions outlining an ulcer regime based chiefly on a full Sippy diet, the use of alkalis and tincture of belladonna and abstinence from alcohol and tobacco. The present paper is chiefly concerned with what happens to the patient from this stage on; that is, commencing with his discharge from the hospital.

FOLLOW-UP RESULTS

It is perhaps best to begin with a presentation of figures regarding the follow-up results in this study. These results were appraised as excellent in 28 cases, as good in 27, as fair in 22 and as poor in 23. Results were considered as excellent when there was no recurrence of symptoms, barium studies showed no ulcer activity and the patient was able to return to and remain at work. They were classed as good when mild symptoms such as occasional epigastric discomfort and belching of gas were experienced but did not interfere with work and were easily controlled by diet. They were described as fair when the patient experienced fairly frequent recurrences of symptoms and when there was occasional loss of time from work or the x-ray showed some evidence of ulcer activity such as marked spasm or an ulcer crater. The results

were considered poor when the symptoms were so constant and severe as to make attendance at work irregular or impossible or in which repeated hospitalizations were necessitated. In this category also fall the cases in which obstruction developed, second perforations occurred or further surgical procedures were performed for the relief of symptoms.

By pooling the excellent and good results on the one hand and the fair and poor results on the other, all the cases may be roughly grouped as satisfactory or unsatisfactory, there being 55 per cent in the former group and 45 per cent in the latter.

"The life history of ulcer can be said to end only with the life of the patient."⁸ Accordingly, it is obvious that the above classification of results does not represent a final analysis, since the average follow-up period was only three years and four months. It is significant, however, that of the patients who fell into the poor or fair categories, the vast majority had experienced recurrences of one sort or another within six months after perforation. In other words, what happens to a patient during the first six months to one year after perforation is a relatively accurate guide to his future course. Few patients who were symptom free for as long as a year had any serious recurrences at a later date.

DURATION OF SYMPTOMS PRIOR TO PERFORATION AS A GUIDE TO PROGNOSIS

It is a well-known fact that acute perforations often occur in persons who have never suffered from ulcer symptoms of any sort. There were 23 such cases in this group. Following perforation, 17 of these enjoyed a satisfactory result, and the remaining experienced difficulties such as to class them as having unsatisfactory results. There were 14 patients who had experienced symptoms for less than six months prior to perforation; 8 of these had satisfactory and 6 unsatisfactory results. In 57 cases symptoms had existed for from six months to many years prior to perforation; of this group, 25 patients experienced satisfactory and 32 unsatisfactory results. In summary, the longer the pre-perforation symptoms the poorer the postperforation results. Thus the presence or absence of an ulcer history prior to perforation has prognostic significance. Unsatisfactory late results were over twice as frequent among patients who had had symptoms for six months or longer as among those who gave no history of pre-perforation symptoms.

There were 31 patients who gave a history of severe symptoms prior to perforation. Of these, 23 had unsatisfactory and 8 satisfactory late results. Thus, a patient who has suffered markedly from ulcer symptoms prior to perforation, regardless of the duration of such symptoms, has about one chance in four of a successful late result.

INFLUENCE OF DIET, ALCOHOL AND TOBACCO ON RECURRENCES

The relation of diet, alcohol and tobacco to post-perforation recurrence of ulcer symptoms was investigated. Surprisingly, among a group of 25 patients who had made no effort to diet the recurrence rate was 40 per cent, whereas of 44 patients who had attempted to follow a diet it was 45 per cent. These figures serve chiefly to emphasize that there are factors that may be more potent than diet in determining the behavior of an ulcer. The patients who were able to remain well without dieting undoubtedly suffered from less virulent ulcer tendencies and found by experience that dieting was unnecessary. On the other hand, the patients who followed their diets for years did so for the most part because they had symptoms either in spite of dieting or whenever the diet was neglected. In short, their ulcers were of a more stubborn and potent nature. Thus, deductions that might be made from a statistical study of the relation of diet to ulcer are of limited significance. The same may be said of alcohol and tobacco. Many patients in this group partook moderately of alcohol and even excessively of cigarettes and yet remained symptom free.

Before the reader takes issue with the preceding paragraph, I hasten to state that there was a group of patients — namely, the 23 whose follow-up results were classified as poor — in whom adherence to diet and abstinence from alcohol and tobacco were of the utmost importance. Indiscretions along these lines in such patients precipitated symptoms almost as constantly as a barometer reflects changes in the weather.

As has been seen, the necessity for following a strict ulcer regime varies from patient to patient, and in any one patient is unpredictable at the outset. It is therefore essential to assume the worst and to insist on a strict regime for every patient indefinitely or until, over a period of years, his ulcer proclivities have been thoroughly assessed. If dietary liberties are allowed and are followed by a recurrence of symptoms, one should close the door forever on such liberties for that patient. It is far wiser to explain to every patient at the outset that he must adhere to an ulcer regime for the rest of his life and that the bars can be let down only at the peril of firing anew the embers of ulcer activity. It is a distressing and frequent experience to learn from a patient in the throes of recurrence that he was told by his physician that dietary restrictions were only an expedient to aid convalescence and could be dropped after that stage.

CORRELATION BETWEEN X-RAY EXAMINATIONS AND SYMPTOMS

Barium studies were first ordered in all cases in which symptoms were severe. Then, since some

patients apparently have ulcers that, although active, are relatively asymptomatic, it was decided that x-ray examination should be made in all cases. Seventy-eight of the 100 patients reported for this examination. Eight additional patients had had such an examination fairly recently, so that barium studies were available in 86 of the 100 cases.

X-ray films were considered positive for ulcer, either active or chronic, under the following circumstances: when an ulcer crater was visualized; when there was pyloric obstruction with a gastric residue; and when persistent marked tenderness and spasm of the duodenal cap were noted in repeated studies.

Measured by the above criteria, x-ray examination showed ulcer activity in 50 (58 per cent) of the 86 patients who were subjected to such studies. Of these 50, symptoms varying from moderate to severe were present in 40 cases (80 per cent), and no symptoms whatsoever had been suffered in 10 (20 per cent). Barium studies were negative for ulcer activity in 36 cases (42 per cent). Twenty (55 per cent) of these patients were asymptomatic and 16 (45 per cent) had suffered from symptoms, which were mild in 12 cases and severe in 4.

It may be seen from the above that the x-ray findings were in complete agreement with the symptomatology in 69 per cent of the cases examined; there was only a slight divergence between these two factors in another 14 per cent, and there was no correlation whatsoever between the symptoms and the x-ray findings in 16 per cent. These latter discrepancies may be explained partly on the basis of inaccuracies in x-ray diagnosis on the one hand and the unquestionable existence of silent ulcers on the other. Deformities resulting from the surgical treatment of the acute perforation are difficult to evaluate and to differentiate from ulcer. Also, the significance of spasm and tenderness is always open to question. In short, it is important to realize that x-ray and fluoroscopy have limitations and that decisions should never be made through these mediums alone.

SECOND PERFORATIONS

Three patients experienced a second acute perforation. One of these patients was sixty-seven years of age. He had suffered from symptoms prior to his first perforation but said that his second came "out of a clear sky" ten months later. He has not followed a strict diet since this last perforation, drinks beer freely, has an active duodenal ulcer as shown by x-ray examination and has recurrent symptoms. Surgery was advised but refused. This patient will undoubtedly experience further trouble.

Another of these patients was seventy-four years of age. He had had symptoms for twenty years prior to his first perforation. The second perforation came eight years later, the interval being marked by transient moderate symptoms. He has had

severe recurrent symptoms, and recent x-ray examination showed an active prepyloric ulcer. This patient improved after strict dieting. Surgery was withheld because of his age and because he presented a poor surgical risk.

The third patient was forty-six years of age. He had experienced symptoms for only fifteen hours prior to his first perforation, which was duodenal. Four years later he experienced a second perforation, also duodenal. The interval was marked by symptoms and failure to follow a diet. A recent barium study showed a penetrating duodenal ulcer. This patient is awaiting gastric resection, which has been advised.

These experiences, although brief, are typical of others reported in the literature.

For several reasons it is concluded that a second perforation should be considered an indication for elective subtotal gastric resection. First, an ulcer that perforates twice is of a virulent, persistent nature and is likely to lead to further grave complications. Second, these patients have not adhered strictly to an ulcer regime in most cases, even though vividly aware of the consequences of laxity in this regard. If a patient does not conform to restrictions after he has experienced one perforation, there is little cause to assume that he will ever do so. Of course, if following an acute perforation a patient is told that an ulcer regime is unnecessary or is told nothing and fails to adhere to a regime through ignorance of it, he cannot be held at fault if a second perforation occurs. He is still entitled to a trial of medical treatment, and not unless he has recurrence under such treatment should he be subjected to surgery.

CARCINOMA IN A GASTRIC ULCER

Carcinoma apparently developed in a gastric ulcer in one of the cases of this series. The patient was fifty years of age. At the time of perforation the lesion was prepyloric and on the lesser curvature. Carcinoma was suspected because of widespread induration, but biopsy showed only chronic inflammation. X-ray films were negative one year after perforation and the patient was free of symptoms for two years, but then began to lose weight and to experience severe epigastric pain and vomiting. The x-ray diagnosis was prepyloric carcinoma. A subtotal gastric resection was performed and an easily resectable colloid carcinoma of moderate size was found in the exact site of the previous ulcer. This patient has remained free of symptoms for four months.

The possibility of the development of carcinoma is certainly to be kept in mind and is an added reason for leaning toward subtotal resection for chronic gastric ulcers, especially in cases in which ulcers have perforated. Walters⁹ believes strongly that surgery is indicated for chronic gastric ulcers in general.

SECONDARY SURGICAL PROCEDURES

Secondary surgical procedures were performed in 11 patients of this series. The indications were as follows: intractability, 5 cases; pyloric stenosis, 4 cases; carcinoma, 1 case; and possible carcinoma, 1 case. Subtotal gastric resection was performed in 7 of these cases. There was no operative mortality, and all these patients have remained symptom free for one to six months. Posterior gastroenterostomy was performed in 3 cases. These patients have remained well for nineteen to seventy-two months.

Partial gastric resection, excluding the ulcer (duodenal) by leaving the pylorus, was performed in 1 case. The pyloric and adjacent antral mucosas were not excised. The patient died following a perforation through the suture line of the gastroenterostomy, the perforation occurring on the nineteenth postoperative day. This patient had had a high gastric acidity, had had two massive hemorrhages in addition to his perforation and had suffered from severe ulcer pains. A subtotal gastric resection including the ulcer was indicated and would probably have been curative.

There are too few cases in this group and the follow-up periods are too brief to make further discussion of the operative results worth while.

There were 12 additional patients whose ulcer symptomatology and x-ray findings were such as to call for subtotal gastric resection. Most of them refused operation. In 3 cases they were such poor risks that surgery had to be withheld.

Combining the 11 patients who had secondary surgical procedures with the 12 who should have had them, one obtains a group of 23 cases in which further surgery was indicated. In other words, in almost one fourth of the cases the follow-up results were sufficiently discouraging to make elective surgery feasible.

COMMENT

Gastric analyses were not routinely carried out in all these cases because of limited time and facilities. It is regretted that the total number of such analyses performed was not sufficient to permit a significant correlation between gastric acidity and the other factors considered in the follow-up study.

The importance of the psychic factor in the causation and aggravation of peptic ulcer is clearly recognized. It was suggestive in many of these cases that personality was a dominant cause of the ulcer difficulties. Since this factor, however, is too complex to lend itself to accurate evaluation it did not seem practical to include it in the study. The psychic factor is also the most inaccessible from a therapeutic standpoint, and it is probable that since this factor exercises a strong influence on gastric motility and secretion,¹⁰ it is the one chiefly at fault in the ulcers that are the most stubborn and virulent in the face of medical treatment.

There seems to be a tendency among physicians and surgeons to cling to dietary efforts through an unwarranted siege of ulcer recurrences. If a patient, following a perforation, has had his condition explained to him and a regime, including diet, outlined and has still had two or more recurrences of serious symptoms in spite of his efforts to follow instructions, the physician should face the facts. He should remember that an ulcer regime has decided limitations, even when followed to the letter. Human nature greatly widens these limitations. If a patient has failed to adhere to a regime several times, there is little justification for supposing that he will do so in the future. The average patient adheres to instructions only so long as he has symptoms. Rather than theorize as to what would happen should the patient adhere strictly to instructions, one should consider what has already happened and make a decision based on facts rather than on theory. Were this done oftener, many more of these patients would come to surgery earlier in their ulcer careers and be spared no end of physical, social and financial suffering. Chronic alcoholic patients and those who are totally uncooperative from a medical standpoint should not be subjected to elective surgery, for surgery is no cure-all. Unless a patient is reasonably careful he may find himself saddled with a marginal ulcer at the gastroenterostomy even though a technically good operation has been performed.^{8, 11}

The 25 per cent of patients suffering from severe recurrences should be subjected to surgery. The indications for surgery in peptic ulcer have been outlined many times. They are as follows: two or more massive hemorrhages, pyloric stenosis with obstruction, intractability and possible malignancy. To these generally accepted indications it seems wise to add the following: patients experiencing acute perforation of an ulcer for the second time, those experiencing acute perforation, preceded or followed by one or more massive hemorrhages, those experiencing severe recurrent ulcer symptoms following perforation and those experiencing perforation as a climax to a protracted ulcer history. It should be stressed that acute perforation is not in itself regarded as an indication for gastric surgery, since over half the patients do satisfactorily on a conservative regime following such perforations. This is an effective answer to those who advocate gastric resection as the procedure of choice at the time of the perforation. Neither should any patient be subjected to elective gastric surgery unless he has given medical treatment a thorough trial and failed to obtain relief.

When elective surgery becomes necessary the same procedure is indicated in ulcers that have perforated as in those that have bled or become obstructive; namely, subtotal gastric resection. This is not only the procedure of choice but is the only one that consistently gives excellent results. By subtotal resection is meant the removal of two

thirds to three fourths of the stomach together with the pylorus, closing the duodenal stump blindly and re-establishing the continuity of the gastrointestinal tract through some form of gastrojejunostomy. If a pyloric or duodenal ulcer is technically hazardous to remove, subtotal resection may be performed, leaving the pylorus and ulcer in situ; this is the so-called "exclusion operation." If it is employed,¹² all antral and pyloric mucosa must be thoroughly excised before closing the pyloric stump. There is one set of circumstances in which gastroenterostomy alone is an acceptable procedure; namely, in an elderly patient having a high degree of pyloric stenosis and an extremely low gastric acidity.

The operative mortality from subtotal gastric resection in the better surgical clinics varies from 2 to 10 per cent. The mortality following this operation is no greater than that following the lesser procedures such as gastroenterostomy.¹² According to Walters,⁹ Wangenstein¹³ and any number of others with wide experience in this field, results following adequate surgery are excellent in 90 per cent or more of the cases. These facts are not new but that they are not fully appreciated by physicians is evidenced by the number of persons suffering from chronic ulcer that are found in the average American community.

In conclusion, two admonitions should be made concerning radical gastric surgery.

First, there are too many surgeons who speak in terms of subtotal gastric resection but who perform a partial gastric resection; who, in other words, resect less than half the stomach for the cure of ulcer. The technic of gastric resection has been standardized and repeatedly published by many of the most competent gastrointestinal surgeons. If one hopes to approach the excellent results appearing in the literature, he must begin by conforming to the principles and technic that yielded these results. Meticulous attention to every detail is essential. Neglect of any one may be fatal.

In the second place, and in line with what has just been said, gastric surgery is no field for the amateur. The consequences of a technically poor operation may be infinitely more distressing than those of a chronic ulcer. The indications for gastric surgery should be considered in relation to the ability of the surgeon.

SUMMARY

A follow-up study of 100 cases of perforated peptic ulcer is reported.

The average length of the follow-up period was three years and four months.

The incidence of perforation was maximum in the fifth decade. There were 97 males and 3 females.

The ulcers were gastric in 54 per cent of the cases, duodenal in 40 per cent, and in 3 per cent

Simple suture was performed for the acute perforation in 94 per cent of the cases.

The follow-up results were considered excellent in 28 per cent, good in 27 per cent, fair in 22 per cent and poor in 23 per cent of the cases.

In cases in which the symptoms prior to perforation are severe or protracted, the prognosis is poor.

Diet, alcohol and tobacco in the majority of cases are not the most important factors governing recurrences; psychic disturbances and lack of co-operation on the part of the patient, however, play significant roles.

Gastrointestinal x-ray studies were in accord with the symptomatology in 67 per cent of 86 cases.

Second perforations occurred in 3 cases. Carcinoma developed in an ulcer in 1 case.

Secondary surgical procedures were performed in 11 per cent of the cases.

Suggestions are made regarding several additional indications for elective surgery in cases of peptic ulcer.

POLIOMYELITIS ON THE ISTHMUS OF PANAMA*

CARL E. TAYLOR, M.D.

ANCON, CANAL ZONE

ENDEMIC poliomyelitis is now recognized as being world-wide in its distribution; it is also thought to be one of the oldest human diseases.¹⁻⁶ In spite of this, only a few recent studies^{7,8} of the epidemiology of endemic cases have been made. The more dramatic epidemic outbreaks, which have appeared principally in the temperate zones during the last fifty years, have been studied with great profit. The knowledge of the epidemiology of poliomyelitis is still extremely incomplete, and studies in endemic areas may contribute to it.

The widespread geographical distribution of poliomyelitis indicates that all races are susceptible to the disease. The relative susceptibility of the various races is, however, difficult to determine. Harmon⁵ summarized the results of studies in the United States and concluded that Negroes seem to be less susceptible to infection than are Whites, but that once infected their mortality rate is apparently higher. Lee⁹ in Hawaii found high incidence rates among Caucasians and native Hawaiians but low rates among Filipinos, Chinese and Japanese. Among the Caucasians there was a fairly general distribution through all age groups, whereas among the Orientals most of the cases were in children under five years of age. In the 1934 epidemic in the Philippine Islands, Hillman¹⁰ stated, most of the cases occurred in white adults.

No previous studies of poliomyelitis on the Isthmus of Panama have been made. The 72 cases

included in this report have been treated at Gorgas Hospital (formerly Ancon Hospital) in the thirty-eight years from 1904 to 1942. During this time there have been over 530,000 hospital admissions, with an average incidence of 1 case of poliomyelitis in 7000 admissions. Most of the cases recognized in the Canal Zone and the Republic of Panama are included in this series, but because of the extreme variability of the base population it has been impossible to derive true incidence rates. Eight hospital cases were not included in the study group because they did not meet rigid diagnostic standards or because the infection had not been contracted on the Isthmus.

SEASONAL DISTRIBUTION

The annual distribution of all cases is recorded in Table 1. For comparison, there is included the total number of cases reported to the Health Department of the Panama Canal.¹¹ The minor discrepancies can be explained either by the fact that some hospital cases were drawn from a slightly wider geographical area than the others or by the fact that some of the cases included in the Health Department records were treated in other hospitals. Local endemicity is clearly indicated by the sprinkling of cases, with an average of slightly greater than 2 cases per year. A minor epidemic pattern is apparent when the cases are carefully analyzed for spatial and temporal proximity. In seven instances there was evidence of contact between

*From the Board of Health Laboratory, Gorgas Hospital.

groups of 2 to 5 cases. These contact groups are listed in Table 2.

The most significant feature of the seasonal distribution, as indicated in Table 3, is the monthly

December 20 1926 to January 2 1927	Panama City	2	3 and 5
November 23, 1931 to January 23, 1932	Silver City and Colon	3 Negroes and 1 Chinese from neighboring localities	1-2
September 27 to October 11 1933	Balboa	2 white girls (close friends)	6 and 9

the incidence in Whites is truly greater than that in Negroes is demonstrated by breaking down the figures for the Canal Zone. Only a few mestizos of Panamanian origin reside in the Canal Zone, and these are customarily included in the Negro or so-called "silver" group in Canal Zone statistics. The Canal Zone School Division has reliable statistics

*The term "race" as used here is a purely utilitarian breakdown of the local color groups. Whites are United States citizens and other Caucasians. West Indian Negroes include the original relatively pure Negro group imported for the construction of the Panama Canal and their children. Panamanians include the mixed Spanish Indian and Negro natives of the Republic of Panama.

on the number of white and negro children living in the Canal Zone from 1928 to the present. The ratio of the total groups is approximately 3 Whites to 5 Negroes. In the 40 cases of poliomyelitis occurring primarily in the Canal Zone the ratio was 5.3. This means that poliomyelitis was two and three-fourths times as common in the Whites as in the Negroes.

AGE

Seventy-two per cent of the patients in this series were five years of age or less, with a median age of three. The contrast in the age distribution of the

TABLE 3 Seasonal Distribution

August	5
September	6
October	8
November	12
December	10

racial groups is striking. Fifty-two per cent of the Whites were five years of age or under, as compared with 85 per cent of the Negroes and 83 per cent of the Panamanians. The white population of the Isthmus of Panama has had an unusually large young-adult group. This has little significance, however, because 83 per cent of the Whites were ten years of age or under and only 2 were over twenty.

SEX

The total group showed the usual distribution of 43 males to 29 females. In the Whites and Pan-

amanians there were twice as many males as females. Among the West Indian Negroes, however, the incidence was equal in the two sexes.

Geographical

In general, the geographical distribution followed that of the population. In the Republic of Panama, Panama City and Colon each had 13 cases, in the Canal Zone, Balboa had 9 and Pedro Miguel 5. Cases came from the interior of

CLINICAL PICTURE

As is true in most endemic areas, the diagnosis of poliomyelitis was rarely made in the absence of paralysis. The average duration of symptoms prior to hospitalization was six and a half days — five days among the Whites, six days among the Panamanians, and eight and a half days among the West Indian Negroes.

The clinical picture was typical, the following symptoms and signs being recorded: fever, 58 cases; nausea, vomiting and anorexia, 32 cases; constipation, 7 cases; diarrhea, 1 case; headache, 15 cases; drowsiness, irritability or coma, 15 cases; mild convulsions or opisthotonos, 8 cases; early positive Brudzinski's or Kernig's signs, 6 cases; and urinary difficulty, 4 cases. Spinal-fluid determinations showed the usual lymphocytosis and increase in globulin.

Only 4 patients were free from paralysis, the diagnosis being made from prodromal symptoms and muscle tenderness in a close contact of a paralytic case. The distribution of the paralyzed muscle groups is shown in Table 4. The average period

of hospitalization was thirty-eight days. The residual paralyzes at the end of this time are also indicated in Table 4.

There were 5 deaths, a mortality of 6.9 per cent. Four of the fatal cases were in Whites and 1 was in a Panamanian. No deaths occurred in the West Indian Negro group. The autopsy reports record the usual neuronal damage and inflammatory reaction.

DISCUSSION

The seasonal distribution of these cases is of interest because of the distinctive climatic conditions prevailing in Panama. The latitude of Panama is about 8° north, well within the tropics. The temperature is monotonously uniform, rarely varying from the narrow range of 68 to 95°F. The incidence of poliomyelitis in most localities shows a direct correlation with warm weather, and it has been stated that in warm climates there is a tendency toward an even distribution throughout the year.¹² Lee⁹ found a seasonal curve in Hawaii, with a prolonged crest extending from February to June. In Panama the variable of temperature is so nearly

controlled that one must search for correlations with other factors.

Panama has only two seasons, the wet and the dry — the latter appearing in January, February and March. With the crest of the poliomyelitis curve occurring in November, December and January one cannot say that either season is particularly favorable for transmission. Instead, it may be that the transition from wet to dry weather is important just as it is thought that the transition from warm to cold weather is important in temperate zones. Most recent studies indicate that rainfall is a negligible epidemiologic factor in other localities.^{1, 4, 5} The seasonal distribution of gastrointestinal diseases in Panama is not well defined. Conner and Bates¹³ reported that from 1919 to 1923 most of the cases of bacillary dysentery at Gorgas Hospital occurred in October, November and December. Macumber¹⁴ stated that in his series of 263 cases of bacillary dysentery in the eleven-year period from 1928 to 1939 there was no significant seasonal variation. A review of his data, however, reveals that the peak month was February with 53 cases and that from October to March there were 170 cases, as contrasted with 93 cases in the six months after the onset of the rainy season. These data show a suggestive correlation between the seasonal distribution of cases of poliomyelitis and bacillary dysentery admitted to Gorgas Hospital.

The racial distribution of poliomyelitis raises several interesting questions. The greater incidence in Whites is difficult to explain. Aycock's¹⁵ autarceologic distinctions suggest intriguing possibilities, and further studies may make it possible to apply them to racial groups. It seems significant that in both Hawaii and Panama the native populations showed involvement in distinctly younger age groups than did the Whites. Reports from the United States,¹⁶ Scandinavia¹⁷ and Australia^{18, 19} all record a distinct shift in the age incidence of poliomyelitis during the last few decades. In earlier epidemics poliomyelitis was characteristically an infantile disease, but most of the recent studies in the predominantly Caucasian large epidemic centers show definitely that older age groups are being afflicted. In Portugal, d'Oliveira²⁰ reported an infantile distribution. A partial explanation that may be proposed hinges on the possibility that abortive attacks or subclinical infections have caused widespread early immunization in the temperate zones in years gone by, and that this condition still prevails among the native populations of the tropics. If one accepts the enteric route of infection, it is not difficult to postulate delayed immunization among Caucasians coincident with an improvement in sanitation. The presence of this nonimmune group would be conducive to the spread of epidemics in the temperate zones. The studies with protection neutralization

tests on monkeys, although these are admittedly crude, lend credence to this hypothesis, since protective bodies have been demonstrated with great uniformity in the blood of the native populations of several tropical and subtropical countries.²¹⁻²⁵ It is hoped that neutralization tests of greater specificity will be developed as a result of Armstrong's²⁶ transmission of the virus to the cotton rat, and that this will permit a more accurate delineation of the true geographical and racial distribution of poliomyelitis.

SUMMARY

Seventy-two cases of endemic poliomyelitis on the Isthmus of Panama have been reviewed.

The crest of the seasonal curve occurs during November, December and January—the end of the rainy season.

Poliomyelitis was two and three-fourths times as common in Whites as in Negroes.

Among the Whites 52 per cent of the patients were five years of age or under, as contrasted with 85 per cent of the West Indian Negroes and 83 per cent of the Panamanians.

There were twice as many males as females among the Whites and Panamanians, but the incidence in the two sexes was equal in the West Indian Negroes.

There were 5 deaths, a mortality of 6.9 per cent. Most of the cases occurred in the large population centers.

X-RAY THERAPY OF THE HEART IN A PATIENT WITH LEUKEMIA, HEART BLOCK AND HYPERTENSION*

Report of a Case

HARRY BLOTNER, M.D.,† AND MERRILL C. SOSMAN, M.D.‡

BOSTON

THIS is the case report of a woman who was followed for years because of vascular hypertension and who later developed myelogenous leukemia and then heart block. Since leukemia is known to infiltrate the heart muscle, it was thought that possibly a leukemic infiltration or a leukemic nodule in the heart was interfering with the conduction mechanism of the heart beat and was the

cause of the heart block. If this were true, it seemed that x-ray therapy applied directly to the heart might cause the block to disappear. There are no reports in the literature of heart block treated in such a manner. Because of the result obtained with x-ray therapy in this case, it appeared of interest to present its details.

CASE REPORT

A 64-year-old widow was known to have had a blood pressure of about 200/100 for 20 years. The blood pressure had been frequently observed during this period, and on rare occasions it rose to 250/110 and dropped to 160/90.

*From the Medical Clinic and Roentgen Department of the Peter Bent Brigham Hospital and the Medical Service of the Beth Israel Hospital.
†Associate visiting physician, Beth Israel Hospital.
‡Clinical professor of roentgenology, Harvard Medical School, roentgenologist, Peter Bent Brigham Hospital.

The records of this case begin in 1925, when the patient was at the old Beth Israel Hospital, where diagnoses of hypertension and chronic myocarditis were made. The examination was negative except for obesity, a precordial systolic murmur and hypertension. A blood Wassermann test was negative. The nonprotein nitrogen was 40 mg. per 100 cc. and the fasting blood sugar 110 mg. The heart was enlarged as shown by x-ray examination, the transverse diameter being 15 cm. and that of the chest 26.5 cm.

In 1933, the patient was admitted to the Beth Israel Hospital for possible cholecystitis, possible coronary disease and hypertensive heart disease. There was a systolic murmur over the precordium. The blood pressure varied from 235/120 to 160/90 and the pulse from 70 to 80. The white-cell count ranged from 19,600 to 9200, with no abnormal cells. The hemoglobin was 80 per cent, and the red-cell count 5,750,000. The body weight was 200 pounds. Electrocardiograms showed left-axis deviation. The urine gave a ++ test for bile on several occasions. The fasting blood sugar was 78 mg. per 100 cc., and the nonprotein nitrogen 32 mg.

From 1933 to 1940, the patient suffered from indefinite abdominal pains, nervousness and many headaches. The heart was regular, with a moderate rough precordial systolic murmur. The blood pressure was usually 200/100. She took many sedatives, and a great deal of Pyramidon for the headaches. Because one of her sons, a physician, feared leukopenia and agranulocytosis resulting from the continued use of Pyramidon, a number of white-cell and differential counts were made; these were found to be normal. In April, 1940, however, the patient had gallstone colic with jaundice, and the white-cell count during this episode ranged from 13,000 to 15,000, returning to normal after the attack disappeared. The weight was 165 pounds, and the pulse 70 to 80.

On March 9, 1941, the patient was admitted to the Peter Bent Brigham Hospital because of marked cyanosis, dyspnea, precordial distress, a temperature of 102°F. and profuse sweating. On admission the pulse was 72 and the blood pressure 204/90. The weight was 141 pounds, and there was evidence of considerable weight loss. The heart was enlarged, and there was a coarse systolic murmur over the precordium. The breath sounds were harsh, and there were a few rales at the lung bases. The liver and spleen were not palpable. The white-cell count was 127,000, with 86 per cent neutrophils, 9 per cent lymphocytes and 5 per cent myelocytes. The hemoglobin was 54 per cent (Sahli) and the red-cell count 2,900,000. The nonprotein nitrogen was 41 mg. per 100 cc. Electrocardiograms (four leads) were normal except for evidence of left-axis deviation.

On the 2nd hospital day the temperature fell to normal, where it remained thereafter. Blood Wassermann and Hinton tests were negative. X-ray examination of the chest showed marked cardiac enlargement and moderate congestion of the lungs, chiefly around the hili. Films of the right shoulder and humerus showed the bones and joints to be rather thin, and the marrow cavity considerably wider and clearer than usual, which it was believed might indicate hyperplastic bone marrow.

Basal metabolism tests on eight occasions were elevated, the first rate being +55 per cent and the subsequent ones varying from +39 to +25 per cent. There was little change in the metabolism after the giving of Lugol's solution. The diagnosis was myelogenous leukemia, hypertension and cardiac decompensation.

The patient was digitalized on entry and then given 0.1 daily. Lugol's solution, 10 drops three times prescribed. X-ray therapy in the form of a n to the trunk anteriorly and posteriorly in of 25 r each — not a large dose. Following cell count dropped to 8650 by March 26;

the entire trunk, alternating front and back, is 5 to 50 r a day to patients with leukemia, and are efficient and better tolerated than concen-spleen or long bones with larger doses. The a filter of 0.5 mm. of copper and 10 mm. of skin distance of 100 cm. At this distance the re trunk. Only the face and head are covered te with a standard Victor chamber with This method has proved extremely hronic leukemias. It does not cause y results in prolonged regressions. In ally are used, but the results are not so

the red-cell count was 3,000,500 and the hemoglobin 88 per cent (Sahli). The patient was discharged improved on April 11 with a white-cell count of 8650 and a weight of 135 pounds. She was instructed to take 0.05 gm. of digitalis daily and 10 drops of Lugol's solution daily, as well as iron.

After this treatment the patient continued to improve, gained weight and was fairly active. The medication was taken as prescribed. The pulse remained at 72, and the blood pressure at 210/100. On September 6, the basal metabolic rate was +14 per cent, the pulse 72, and the weight 155 pounds. The white-cell count was 10,600, the hemoglobin 70 per cent, and the red-cell count 4,310,600. On October 21, however, when the white-cell count was 14,500, the patient began to feel tired. The white-cell count subsequently increased slowly, reaching 31,900 by March 1, 1942. X-ray therapy was again given on March 4 and 5 in the form of a spray to the trunk anteriorly and posteriorly in two treatments of 25 r each, and in 9 days the white-cell count dropped again to 9000 and the patient felt much better.

In April the patient again commenced to feel tired, weak and conscious of her heart beat and began to have a slow pulse (36 to 48), which persisted until August, the blood pressure remaining at about 210/100. The digitalis was omitted shortly after the pulse slowed, but in spite of this, the low rate persisted even though there was no coronary pain or decompensation. On July 8, when the white-cell count was 19,600, electrocardiograms showed a 2:1 heart block and left-axis deviation.

At that time it was thought that in the presence of leukemia, a leukemic nodule or infiltration involving the bundle of His might be the cause of the heart block and that x-ray therapy to the heart might cause the nodule to decrease in size and the block to disappear. It was believed that if x-ray therapy of the heart had an effect, this would begin after four or five days of treatment, because following such a period of x-ray therapy in leukemia the white-cell count usually falls appreciably. Consequently, it was decided to treat the patient in this way in the hospital. She was admitted to the Peter Bent Brigham Hospital on August 6 for x-ray therapy of the heart and was discharged on September 2. The pulse was 38 and the blood pressure 208/80. The weight was 165 pounds. The heart action was slow and regular. A third heart sound was audible, which may have been due to auricular contraction and had been present since the heart block appeared. In addition, a moderate rough systolic murmur was present over the precordium. Electrocardiograms again showed a 2:1 heart block and left-axis deviation. The white-cell count before x-ray therapy ranged from 22,000 to 24,500. The hemoglobin was 89 per cent (Sahli) and the red-cell count 4,490,000. The basal metabolic rate before x-ray therapy was +15 and +20 per cent. The blood urea nitrogen was 28 mg. per 100 cc.

X-ray therapy was directed to the heart on August 11, 12, 13, 17 and 25. The treatments given directly to the cardiac area were at the standard target-skin distance of 50 cm., using 200 kv., and a filter of 0.5 mm. of copper and 1.0 mm. of aluminum. With these factors the ionization rate measured in air was 65 r per minute. Daily doses of 200 r to the precordium were given, using a cone 15 cm. in diameter. The total skin dose in five treatments during 15 days was 1000 r.

On August 14, the pulse, which had been between 36 and 42, rose to 72 to 80 during auscultation and the third heart sound disappeared. The heart again went into block, however, and apparently was in a transitional state of being in and out of block. Electrocardiograms were taken of these phases during auscultation (Fig. 1). The pulse remained at about 80 much of the time and periodically dropped to 42. The murmur of the heart was of less intensity when it was unblocked than when it was blocked.

During the period of hospitalization a 7-foot film of the heart gave evidence of fairly marked cardiac enlargement. Fluoroscopy showed a slow beat of large amplitude with systolic expansion of the right pulmonary artery. The right auricular beat appeared in approximately 2:1 rhythm when the patient was in heart block. In the mitral annulus fibrosus there was an area of calcification that moved with the auricular beat and not with the ventricular pulsation. The heart had a transverse diameter of 17.8 cm. and the chest an internal diameter of 29.5 cm. Re-examination of the heart by x-ray when it was not in block showed its size and shape to be almost identical with those noted 11 days previously when the heart was in block.

The patient was discharged on September 2. The pulse remained at a level of 72 for 6 days and then dropped to 42, where it remained (Fig. 2). It stayed at this level until after further x-ray treatment of the heart, beginning on Novem-

ber 23, when the heart again went into 2:1 block, with a pulse of 48. When the white-cell count increased to 27,000 on February 4, it was decided to give x-ray spray therapy to the trunk anteriorly and posteriorly to discover whether reducing the

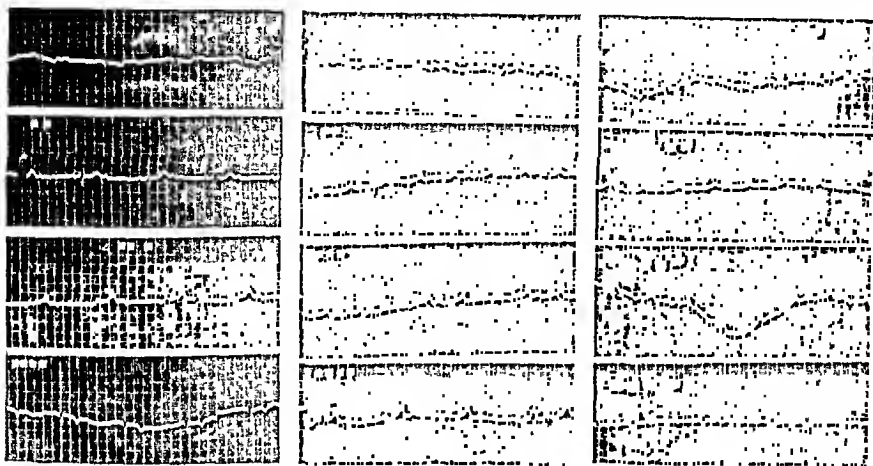

FIGURE 1. *Electrocardiographic Changes after X-ray Therapy.*

The tracings on the left, taken on August 11, before treatment, show 2:1 heart block with an auricular rate of 84 and a ventricular rate of 42. The middle tracings, taken on August 14, after treatment, show that the heart was in and out of block, normal sinus rhythm alternating with 2:1 block, T_4 is upright. The tracings on the right, taken on August 19, show normal rhythm with a rate of 77; T_4 is inverted. In all sets, there is evidence of left-axis deviation.

ber 23. Electrocardiograms repeated on several occasions when the pulse rate was slow showed a 2:1 heart block.

On November 23, the white-cell count increased to 32,500 and x-ray therapy of the heart was again given as well as on three subsequent occasions at weekly intervals. Three

white-cell count would affect the heart block and pulse. Consequently this treatment was given on February 4, 17 and 25 and March 8. As a result, the white-cell count dropped to 7800, where it remained until May 24, when it was 11,800. During this time, even though the white-cell count was di-

FIGURE 2. *Effect of X-ray Therapy of the Heart on the Pulse and White-Cell Count.* The black blocks represent the dates on which x-ray therapy of the heart was given. The pulse rate had previously varied from 36 to 48 for a period of five months.

days later the pulse rose to 72 for 5 minutes and then dropped to 44. X-ray therapy of the heart was repeated on December 1, 7 and 15 (Fig. 3). The white-cell count dropped to 19,800 on the last date and the pulse was 72 for several minutes. From December 17 to January 18, 1943, it ranged from 72 to 80 except for a 3-day period in December when it was 48. The blood pressure was 200/100. Subsequently

minished to normal, the pulse remained at 48, although on two occasions after exertion it rose to 72 for a few minutes. The blood pressure remained at 200/100 until May 24, when it rose to 270/90. The patient had felt faint with considerable abdominal distress and was acutely conscious of her heart beat. She stated she had felt best after she had had x-ray therapy of the heart and when the heart was not in block.

On May 29, the blood pressure rose to 300/100 and a right hemiplegia occurred. The patient became unconscious and died within 3 hours.

COMMENT

This was an interesting case, with hypertension and with severe and frequent headaches for many years, for which the patient took a great deal of Pyramidon. In March, 1941, it was found that she had myelogenous leukemia, which readily responded to spray x-ray therapy to the trunk anteriorly and posteriorly. A year later, the patient developed a 2:1 heart block that persisted for five months. It was believed that this block was due to a leukemic infiltration or nodule involving the bundle of His. Consequently, x-ray therapy was directed to the heart and the heart

tases,^{2,3} and cardiac arrhythmias may occur in tumors of the heart.^{4,5}

The cause of the leukemia in this case is unknown, although one son, a physician, believed that it was due to the long-continued use of large doses of Pyramidon. A report in relation to Pyramidon was made by Delore and Borgomano,⁶ who observed leukemia in a worker who for five years had extracted Pyramidon with benzene; the disease may have been due to the Pyramidon rather than to the benzene.

SUMMARY

This paper reports the case of a woman who had hypertension for twenty years and leukemia for two years. For five months she had a 2:1 heart block that was believed to have been due to a

FIGURE 3. Effect of X-ray Therapy of the Heart and Trunk on the Pulse and White-Cell Count.

The black blocks represent the dates on which x-ray therapy of the heart was given; the black circles, the corresponding dates for x-ray therapy of the trunk. For ten weeks previously, the pulse had varied from 42 to 48.

block disappeared intermittently for seventeen days and then persistently for seven days. When the heart block reappeared and persisted again for over two months, x-ray therapy was applied to the heart, and again the heart block disappeared intermittently for a month and then persistently for twenty-three days. The heart block then reappeared, and a month later when the white-cell count was 24,900 x-ray therapy was given to the trunk. Although the white-cell count remained at a normal level for three months, the heart block persisted. It is known that heart block may appear and disappear without obvious cause. The results in this case, however, strongly suggest that x-ray therapy applied directly over the heart, by its effect on a leukemic infiltration of the heart, which involved the conduction mechanism, caused the heart block, which had been present for five months, to disappear on two occasions.

Leukemic infiltrations in the myocardium are not uncommon and rarely lead to alteration in the mechanism of the heart action.¹ Leukemic infiltrations may, however, produce, besides diffuse infiltrations, definite nodules resembling tumor metas-

leukemic nodule or infiltration involving the bundle of His. X-ray therapy applied to the cardiac area was followed by a disappearance of the heart block for several days on two occasions. Finally, on a third occasion when the white-cell count was elevated and the heart was blocked, x-ray therapy applied to the trunk did not cause the heart block to disappear even though the white-cell count was reduced to normal.

It is suggested that x-ray therapy of the heart caused the heart block to disappear by its effect on a possible leukemic infiltration of the heart that involved the conduction mechanism.

MEDICAL PROGRESS

SPONTANEOUS, THREATENED AND HABITUAL ABORTION: THEIR PATHOGENESIS AND TREATMENT*

ARTHUR T. HERTIG, M.D.,† AND ROBERT G. LIVINGSTONE, M.D.‡

BOSTON

SPONTANEOUS abortion, together with its intimately related syndromes of threatened and habitual abortion, is a frequent and therefore important complication of pregnancy. A voluminous literature not only attests to these facts but also emphasizes the general biologic complexity of the condition.

That man is not the only species subject to this complication of pregnancy is shown by studies on embryonic pathology in mammals (Corner¹). Thus, the domestic sow shows a fairly constant ovular mortality of approximately 30 per cent, as judged by the discrepancy between the number of ovulated ova — based on counts of corpora lutea — and the number of, such potentially fertilizable ova that reach full term as viable living fetuses. A similar situation obtains in laboratory animals such as the rat, rabbit and ferret. A comparable ovular mortality has been postulated in domestic animals, such as cows and mares, that ordinarily liberate but one ovum at the height of estrus. It has long been known that a normal pregnancy does not necessarily result from the single mating of a known fertile pair of such domestic animals. Such failures, according to Gowan,² may amount to 20 to 25 per cent in beef and dairy cattle, and are ascribed to disasters that may overtake the ovum at any time from its ovulation through fertilization and subsequent development. Approximately one third of the 30 per cent defective ova in animals that produce litters, constituting about 10 per cent of the total number of ova thus liberated, reach a stage in their development that coincides with a clinically recognizable pregnancy. The other two thirds, or 20 per cent of all ovulated ova, may fail to become fertilized, to undergo segmentation or to implant. Thus, the 10 per cent that do implant and that develop to a variable degree but ultimately die before full term are closely analogous to the 10 per cent (approximately) of human pregnancies that end in abortion.

Rock³ in a review published in this journal in 1940 summarized all the essential aspects of abortion. It is the purpose of the present article to

stress the pathogenesis of spontaneous abortion and to summarize the recent literature with respect to the treatment of the theoretically preventable forms of this condition, namely, threatened and habitual abortion. Stated differently, it is an attempt to trace the various pathologic stages leading up to a spontaneous abortion and to determine what proportion of such abortions are treatable, at what stage in their development such treatment must necessarily be instituted to save the pregnancy and what constitutes modern methods of treatment.

It is apparent that any spontaneous abortion goes through various stages, including the threat to abort as evidenced by bleeding and uterine cramps, and progresses ultimately to an inevitable abortion that may be either complete or incomplete. It is furthermore evident that during this stage, when the patient is threatening to abort, it may be difficult or impossible to determine clinically whether or not the pregnancy can be salvaged. Hence, all threatened abortions must, in the absence of more precise clinical signs, be considered salvageable until proved otherwise. A certain proportion of such abortions, however, subside without any specific treatment other than bed rest and mild sedation, the remainder being completed. The latter pregnancies are therefore the only ones that yield information about the causes of abortion. In a large proportion of cases, pathological examination of such abortuses gives a definite clue as to the cause of the abortion. My⁴ analysis of 1000 abortuses forms the basis for the statements on the pathogenesis of spontaneous abortions.

It is evident that any rational treatment of threatened or habitual abortion must be directed toward saving the pregnancies that are fundamentally salvageable when the patient is first seen, even though the physician does not at that time know whether or not such a pregnancy can be saved. For this reason, the results of the treatment of threatened and spontaneous abortion reported in the literature should be interpreted in the light of the foregoing, for it must be stressed that a certain proportion of such patients will not abort anyway and a certain proportion will abort no matter what the treatment. The percentage of successfully treated threatened and habitual abortions must therefore consist of the group of pregnancies that

*From the Boston Lying-in Hospital and the Departments of Pathology and Obstetrics, Harvard Medical School.

‡Former house officer, Boston Lying-in Hospital.

would not have aborted anyway, in addition to those that are salvageable when the patient is first seen. This percentage would be ascertainable if the various factors were known. Unfortunately, at the present time not all such factors are known, or at least agreed on, by the various authors writing on the subject.

INCIDENCE

Spontaneous Abortion

It is generally agreed by most authors that by a conservative estimate 25 per cent of pregnancies end in abortion of induced, therapeutic or spontaneous origin.³ The latter cause accounts for one third of the total group, or approximately 8 per cent of all pregnancies. Among other authors, Mason⁵ and Silbernagel and Burt⁶ place this figure at 6 and 13 per cent, respectively. I⁷ have examined pathologically all the abortuses from a large private obstetric practice in Boston over a period of six years, and have found the incidence of spontaneous abortion to be 10.6 per cent of the 1150 cases of full-term pregnancy and spontaneous abortion combined. If the cases of therapeutic abortion, hydatidiform mole and ectopic pregnancy are included in the total, the proportion of the total number of obstetric cases ending in spontaneous abortion becomes 10.4 per cent. In a report on the treatment of habitual abortion with vitamin E authorized by the Council of Pharmacy and Chemistry of the American Medical Association I⁸ summarized the findings of various American authors (Plass, Brunner, Newton, Simmons and Kopp) and concluded that 9.8 per cent of all pregnancies terminate in spontaneous abortion. It seems fair, in view of the foregoing data, to assume that approximately 10 per cent of all pregnancies abort spontaneously.

Threatened Abortion

In order to evaluate properly the results of the treatment of threatened abortion, it is necessary for the physicians who treat it to have a uniform concept of what the condition is. Unfortunately, not all therapeutic reports in the literature appear to define threatened abortion in the same terms. For example, Mason⁵ and Soule⁹ consider hemorrhage or uterine cramps or both to constitute a threat to abort, whereas Silbernagel and Burt⁶ state that a threatened abortion is always accompanied by uterine bleeding, either with or without uterine cramps. Rutherford¹⁰ required that the patient pass an amount of blood by vagina—excluding cervical and vaginal lesions—sufficient to make a stain 5 cm. in diameter on a vulvar pad before the case was classed as a threatened abortion. It seems by a priori reasoning that the threat to abort is less serious if the patient merely has uterine cramps instead of uterine bleeding, either with or without cramps. Hence, the results of any therapy in the first group may reasonably be expected to be better than those in the second group.

The incidence of threatened abortion is variable, as one would expect from such variations in the concept of the condition. It occurred in 0.94 per cent of 24,289 pregnancies at the New York Hospital (Javert and Stander¹¹) over a period of eight and a third years. Paine¹² states that 3.8 per cent of the patients at the Evangeline Booth Hospital in Boston threatened to abort, a figure that is in essential agreement with that of Rutherford¹⁰ of 4.0 per cent for the Boston Lying-in Hospital.

Since all patients who ultimately abort must necessarily threaten to abort for a variable period before they complete the process, the true incidence of threatened abortion must be at least as great as the incidence of spontaneous abortion. In the light of this fact, and considering an accepted incidence of 10 per cent for spontaneous abortion, the incidence of threatened abortion appears to be surprisingly low. This discrepancy is rationalized only when one considers the incidence of threatened abortion in private practice. Silbernagel and Burt⁶ state that 140 (16 per cent) of their 870 private obstetric patients threatened to abort, whereas 10.9 per cent of Mason's⁵ private patients did so. The only explanation for this discrepancy between the figures of large obstetric hospitals and those of private obstetric practitioners lies in the fact that private patients consult their physicians much earlier in pregnancy than do a comparable group of clinic patients. Hence, many of the potential clinic patients who are only two to three months pregnant have threatened to abort, and indeed have carried out that threat before coming to the hospital for their initial visit. That this assumption is true is shown by the frequency with which clinic patients give a history of having had a previous abortion at home and having consulted their physician or hospital, if at all, only because of continued bleeding due to incompleteness of the abortion.

If it is difficult to obtain uniformity of opinion on what constitutes a threatened abortion and on how frequently the condition actually occurs, it is even more difficult to obtain figures that are in uniform agreement regarding the prognosis of the pregnancy when once it threatens to abort. Irving¹³ states that over half the patients who threaten to abort ultimately go to term and deliver normal babies. Other authors, however, are by no means so sanguine in their outlook. Thus, Javert and Stander¹¹ found that 100 per cent of their untreated threatened aborters aborted. Silbernagel and Burt⁶ found that only 6 per cent of their untreated threatened aborters went to term, whereas 24 per cent of Rutherford's¹⁰ 91 cases failed to abort.* Parish¹⁴ and Falls and his co-workers¹⁵ are in rela-

*It must be pointed out, however, that endometrial biopsies were taken from the lower uterine segment of these patients in an attempt to determine the state of the endometrium and thus gain some idea of the inevitability of the abortion. The concept back of this study was based on my continued observation over a number of years that all abortuses show a marked degree of decidual sinusoidal thrombosis, with resultant decidual necrosis and hemorrhage. It was argued that, with the presence of this triad of pathologic signs, the prognosis for a pregnancy was poor—even though the ovum had not yet aborted.

tively close agreement that 57 and 39 per cent, respectively, of their control cases of threatened abortions go to term. Walsh, in discussing Paine's¹² paper, makes a general statement that nearly half the threatened abortions are saved. Bach and Winkler,¹⁶ according to an abstract in the *Journal of the American Medical Association*,¹⁷ state that 50 (65 per cent) of their 74 control cases of threatened abortion continued to term. Some doubt may be cast on this figure, because in another abstract¹⁸ of the same article the title is slightly different and includes cases of habitual as well as threatened abortion.

It appears that such a variation in the prognosis of untreated threatened abortion will have to be rationalized and an agreement reached on what the true prognosis of untreated threatened abortion is before the real worth of various specific therapies for this condition can be evaluated.

Habitual Abortion

This condition, according to the report of the Council on Pharmacy and Chemistry of the American Medical Association,⁸ "is defined by Bishop as premature delivery on more than one occasion before the fifth month of gestation not due to discoverable disease, organic cause or artificial induction." This concept is not entirely in accord with mine, since it is possible to have recurrent spontaneous abortion caused by discoverable disease and an organic factor, as will be shown later in the section on pathogenesis. A more rational approach to the problem would be to consider a true habitual aborter as one who "has had at least two consecutive abortions."¹⁸ If this last definition is further clarified to include the phrase "two consecutive spontaneous abortions," I shall be in perfect accord with it.

The incidence of habitual abortion may be expressed in terms of its proportion of total pregnancies or as a simple percentage of all spontaneous abortions. Thus, the incidence given by Bishop⁸ is 0.41 per cent of a series of 2687 pregnancies, whereas Malpas's¹⁹ comparable figure is 1.0 per cent. In Javert and Stander's¹⁴ series of 1648 abortions admitted to the New York Hospital, 59 (3.6 per cent) of the patients gave a history of having had three or more abortions. It is not evident from the latter author's data what proportion of either the habitual or the total series of abortions were induced. If one admits that 35 per cent of all abortions are spontaneous in origin (see above) and assumes that all these 59 cases were true spontaneously recurrent abortions, 9.8 per cent of the total number of Javert and Stander's spontaneous abortions were due to recurrent causes. Actually, the proportion of habitual abortions in all spontaneous abortions probably lies somewhere between the 3.6 and 9.8 per cent. Similarly, if Bishop's⁸ figure of 0.41 per cent as representing the absolute incidence of

habitual abortion in pregnancy is used and it is realized that 10 per cent of all pregnancies abort spontaneously, the proportion of spontaneous abortions that are due to recurrent factors is 4.1 per cent. These figures are in general agreement with the conclusion in the report of the Council on Pharmacy and Chemistry,⁸ based on Whitehouse's²⁰ data, "Although the diagnosis of repeated abortion might have been made in from 4.5 to 6.8 per cent of the cases considered in this analysis, it seems likely that at least 2.9 per cent of the women were liable to repeated abortion and possible that 7.7 per cent may have been subject to the probability of abortion as great as 0.84."

PATHOGENESIS

Threatened Abortion

There are no definite statements in the literature concerning the underlying pathologic anatomy of this condition. It seems logical, however, to assume that the endometrium shows the same fundamental picture as in spontaneous abortion, namely, thrombosis of decidual sinusoids with resultant necrosis of and hemorrhage into the decidua. The degree of this process is probably not so marked in threatened as in spontaneous abortion.

These assumptions on my part are based on observations made on the endometrium (decidua) of therapeutically removed early pregnant uteri at the Boston Lying-in Hospital and the Free Hospital for Women. Beneath the developing placentas of such pregnancies one almost invariably encounters a small area of necrotic decidua with its associated thrombosed sinusoids. Thus, there exists even in anatomically normal pregnancies a mechanism that may lead to bleeding from the placental site and hence cause the clinical syndrome of threatened abortion.

The cause of this disturbance in the placental site of a normal pregnancy, which is beyond the scope of this paper, is probably the continual encroachment of the growing placenta on the endometrium of the placental site. It is probably a matter of chance, therefore, whether the necrosis is extensive enough to cause bleeding and, if so, whether the blood will escape into the vagina and thus become clinically evident. It becomes apparent, in the light of these observations, that not all uterine bleeding necessarily means an inevitable abortion; nor, on the other hand, does it surprise one that a significant percentage of spontaneous abortions may produce anatomically normal ova that are salvageable if proper treatment is instituted in time.

Spontaneous Abortion

The data in the subsequent section are a summary of an analysis of 1000 spont.

miscarriages examined pathologically at the Boston Lying-in Hospital during a six-year period. The original data were published by me⁴ in collaboration with Sheldon in 1943.

During this study it became apparent that two main factors were operating to produce a spontaneous abortion, namely, those traceable to defects or abnormalities of the ovum and those due to maternal causes. In the former category were 617 abortuses, or 61.7 per cent of the series, whereas the remaining 383, or 38.3 per cent, were in the latter category.

It is obvious that, no matter how detailed is the pathological examination of the abortus or how perfect is the clinical history, — which many histories in this series were not, — this approach to the problem of spontaneous abortion is subject to error. Some of the interpretations, therefore, may be open to question. This is so if only for the reason that the pathological study of the abortus alone leaves out one, if not the most important, aspect of the problem — the pathological examination of the uterus. Furthermore, these studies are not correlated with any associated endocrinologic studies of the patient — another important aspect of the problem. Be that as it may, they furnish some clue to the essential problem in the pathogenesis and treatment of spontaneous abortion; namely, what sort of ova spontaneously abort and how many of them could theoretically have been salvaged when the patient was first seen by the physician.

Ovular factors. The largest single group of causes of spontaneous abortion is that which results in the production of a blighted or pathologic ovum: that is, one in which the embryo is absent or extremely defective. In this category were 489 abortuses, or 48.9 per cent of the total number. This over-all classification does not take into account the bitter controversy that has raged for years regarding the factor or factors that cause these ova ultimately to become pathologic. It is not within the scope of this article to decide whether all these ova were defective from the beginning (germ-plasm defects) or whether one or more environmental factors acted on a normal fertilized ovum, causing it to become pathologic. Suffice it to say that my studies with Rock²¹ have shown that intrinsically pathologic human ova exist soon after implantation. Four such specimens, together with an abnormally implanted but otherwise normal ovum, have been recovered from surgically removed uteri prior to the first missed menstrual period. Each of these specimens was yielded by patients who had previously had several normal pregnancies. Their fertility, therefore, had been established and general abnormalities of uterine environment ruled out.

Aside from the fact that this group of blighted ova constitutes almost half the abortuses examined, an additional fact of importance is that approximately two thirds of these ova showed variable

degrees of hydatidiform degeneration of their chorionic villi.²² In rare cases such ova, tending to abort in their tenth week of gestation, for reasons not understood, remain in the uterus and become a classic hydatidiform mole. This fact must be kept in mind in treating any case of threatened abortion, for the physician may unwittingly convert an inevitable abortion of such a pathologic ovum into a true hydatidiform mole. The probability of such an occurrence is remote, but it is nevertheless possible. One such patient, who had been treated for threatened abortion for the previous six months by a local physician, came to the Boston Lying-in Hospital and was delivered of a hydatidiform mole. The chance that this mole might have developed spontaneously cannot, of course, be ruled out.

In the series of abortuses under consideration, there were 32 (3.2 per cent) that showed localized anomalies — usually of the nervous system. That such anomalies are not incompatible with a full-term delivery and even some degree of extrauterine life cannot be gainsaid. The incidence of such anomalies was, however, four times as great as is the incidence of such anomalies in full-term deliveries at the Boston Lying-in Hospital. With these facts in mind, it is well for the physician treating threatened abortion to remember the additional possibility of bringing to term a monster that would otherwise have aborted.

Javert and Stander,¹¹ in commenting on this problem, state that although infants born of mothers who have threatened to abort are not necessarily malformed, the tendency may be greater than otherwise. Thus, Kotz et al.,²³ quoted by Javert and Stander,¹¹ gives 4.9 per cent as the percentage of malformed fetuses born to a group of mothers treated for threatened abortion, whereas these authors¹¹ found that in 27,000 deliveries at the New York Hospital only 2.95 per cent of the infants were so afflicted. Greenhill²⁴ found the average incidence of fetal abnormalities in twenty-six clinics to be only 0.94 per cent. The same author, however, found that forty clinics showed an average of 2.75 per cent fetal abnormalities in cases of placenta previa. In the light of these various data, it appears that treated cases of threatened abortion run an increased risk of producing a malformed infant, although Shute,²⁵ quoted by Silbernagel and Burt,⁶ denies that such a mother runs an increased risk.

Various abnormalities of the placenta, all associated with normal embryos, constitute 9.6 per cent of these 1000 abortuses. Various derangements of placental formation and function are found in this group, but the commonest ones are the circumvallate placenta (4.5 per cent), hypoplasia of the placenta (2.0 per cent) and the so-called "Breus's mole" (1.9 per cent) — the latter a normal placenta in which the maternal blood has clotted, thereby causing fetal death.

The common denominator with respect to the cause of the abortion in most of these abnormalities, as well as in the remaining ones of the group (3.2 per cent), is fetal death. Some of the *cremavallate* placentas, however, when they separate prematurely at their margin, cause the onset of premature labor, which results in the delivery of a living but nonviable fetus.

Since most of the abortuses in all three of these major groups of ovular abnormalities could not have been salvaged, because fetal absence, deformity or death initiated the train of signs and symptoms that brought the patient to the physician, any form of therapy would have been useless. It is manifestly impossible to determine clinically which threatened aborters are going to abort and, if they are destined to do so, which of the abortuses can theoretically be salvaged. It is therefore necessary to treat all patients threatening to abort until either they become symptom free or their abortion becomes inevitable.

Maternal factors. In the next group of abortuses, those associated with maternal causative factors, there are a number of cases in which the pregnancy might have been salvaged. The criterion on which this assumption is made was the presence of a normal, living fetus at the time the patient was first seen by the physician.

The group of criminal abortions is necessarily small and constitutes 2.1 per cent of the total. It is to be expected that criminally induced abortions would not be numerous in a group of spontaneous abortuses submitted to the pathologist in an attempt to discover the cause of the abortion. I have, however, been interested in the pathologic sequence of events in criminally induced abortions and have attempted to acquire such material, thus accounting for the few cases of this type among the group of otherwise spontaneous abortions. The figure of incidence is therefore entirely erroneous and actually much lower than exists throughout the country. Suffice it to say, for the sake of comparison, that the pathologic picture is often one of premature rupture of the membranes, followed by acute bacterial inflammation of the chorion, amnion, placental villi and decidua.

Uterine abnormalities constituted 6.4 per cent of the total. Low implantation of the placenta accounted for the vast majority of these cases (5.6 per cent of the entire 1000). Other causes of abortion embraced such diverse factors as placenta accreta, bicornuate uterus, multiple leiomyomas and fixed retroversion of the uterus. In spite of the fact that all these fetuses within the low-implanted ova were normal and many were living when the patient was first seen, the practical difficulties of

prolonging the pregnancy to a time when the fetus becomes viable are obvious. These difficulties, furthermore, do not include the later ones associated with the management of placenta previa. Comment has already been made on the increased incidence of fetal abnormalities associated with placenta previa.²⁴ Doubtless these are due to interference with the oxygen supply and other vital factors during the early critical period of embryonic growth.

Febrile and inflammatory disease, a small but important group, constituted 2.0 per cent of the total series and included local bacterial inflammation of the endometrium, both acute and chronic, as well as general febrile states from various causes. The commonest cause of abortion in this group was acute bacterial endometritis (1.3 per cent). Fever of unknown etiology (0.5 per cent) was the next commonest cause, and such diverse causes as smallpox, chronic endometritis and pyelitis each caused one abortion (0.1 per cent). That general febrile states can and do cause spontaneous abortion is attested by the number of pregnant patients who aborted during the influenza epidemic of 1918-1919.

It is worthy of comment that local inflammation plays a relatively small part in the etiology of spontaneous abortion. This is in contrast to the views advanced in 1921 by Mall and Mcyer,²⁸ who ascribed to inflammation a prominent role in the causation of abortion. It appears that they misinterpreted the leukocytic response to sterile decidual necrosis following thrombosis of sinusoids—a universal finding in all spontaneous abortions of whatever etiology.

A small and heterogeneous group (1.2 per cent) is formed only as a matter of convenience. It includes such diverse causes as radiation effect on ovaries (0.2 per cent), erythroblastosis fetalis (0.3 per cent), surgical removal of a corpus luteum (0.4 per cent), blood dyscrasias (0.1 per cent) and interference with the circulation of the umbilical cord (0.2 per cent).

These cases require little comment other than to note that some of them (the previously radiated cases), probably could not have been salvaged, whereas others, such as those due to surgical removal of the corpus luteum, offer ideal situations in which to employ the substitution therapy of progesterone injection.

Patients with anatomically normal ova constituted 26.6 per cent of the entire series. Since a large number of them — approximately two thirds — possessed not only normal but living fetuses when first seen by the physician, it is within this group that hope for successful therapy lies. Because of the importance of this group, the various factors apparently concerned are listed in some detail (Table 1).

For a detailed discussion of this group the reader is referred to the original paper¹ in these papers appeared. Suffice it to

*It may be questioned as to why low-implanted placentas should be considered as due to any maternal factor. The reason for assuming this is that increased risk of placenta previa in multiparae is not due to the placenta itself but to the maternal pelvis. The placenta is at the lower end of the uterus at the time of delivery. The post partum haemorrhage is due to the placenta being pulled back to its usual position in the maternal cavity rather than in the cervical.

though two thirds of these fetuses were macerated at the time of the abortion, nearly half were living when the symptoms or signs or both that brought the patient to the physician began. This fact is determined by knowing the date on which such symptoms or signs began and by calculating the

TABLE 1. Classification of Cases with Anatomically Normal Ova.

CLASSIFICATION	No. of Cases
Anatomically normal ova without disease:	227
Fetus macerated	146
Fetus living	81
Acute chorionitis, consistent with spontaneous premature rupture of membranes:	14
Fetus macerated	9
Fetus living	5
Positive Hinton and Wassermann tests (syphilis probably not responsible for abortion)	3
Infarction of placenta, extensive (all fetuses macerated)	13
Toxemia of pregnancy:	5
Fetus macerated	3
Fetus living	2
Trauma	
Internal:	
Two successive endometrial biopsies on sterility patient not known to be pregnant	1
Exploratory laparotomy	1
Intrauterine injection of lipiodol 7 weeks prior to last menstrual period	1
External:	
Automobile accident (a bona fide cause of this abortion)	1
Total	266

menstrual age of the fetus from the classic tables of Streeter.²⁷ By this means it is possible to determine whether the fetus was younger or older than the duration of pregnancy when bleeding first began. If the former was true, the fetus was dead prior to the onset of bleeding, whereas if the latter proved to be the case, the fetus was living after the onset of bleeding. It becomes evident, therefore, that two thirds of these pregnancies with normal ova were theoretically capable of being salvaged instead of merely the apparent one third that showed living fetuses at the time of the abortion.

Considering all types of abortuses in which there was a normal, albeit sometimes a dead, fetus at the time of abortion, it is apparent from these figures that 47.9 per cent of this series of 1000 cases could be so classified. Furthermore, if one applies to this group the rough theoretical salvage rate of two thirds of such cases, one finds that one third of all spontaneous abortions contain a normal living fetus at the time the patient is first seen. This is perhaps erring in favor of the therapeutists, although the figure is not far from the actual truth. It is from such a group of cases, together with those of threatened abortion that would not have aborted anyway, that one must draw the group of successfully treated threatened aborters. It is difficult to see how a successful case could come from any other group unless, perchance, it came from the group about which there might be differences of opinion whether it really contained *bona fide* cases of threatened abortion.

Habitual Abortion

Few data exist on the pathogenesis of habitual abortion other than those contained in such a series

as that discussed above in the section on spontaneous abortion. What data exist in my series can be summarized by saying that the causes of habitual abortion are apparently as varied as those resulting in a chance or single spontaneous abortion. Correlated with the clinical definition of the disease, as one resulting in two successive spontaneous abortions, is the repetition of pathologically identical or similar causes in successive abortuses. Thus, in a series of 14 patients, each of whom had two successive spontaneous abortions that were examined pathologically, each pair of abortuses appeared to have occurred following the same or similar causes. A habitual aborter, therefore, is a patient who tends to repeat a given clinicopathologic syndrome rather than to experience it only once.

Because of this fact, the problem of treating habitual abortion has at least some justification for being approached optimistically by the physician. If the patient is a known habitual aborter, it is at least theoretically possible to determine something of the probable cause or causes of future abortions and to set about treating the condition at the time of conception — an advantage not possessed by the physician treating a threatened abortion which may, from the beginning of signs and symptoms, be inevitable.

TREATMENT

This section concerns the treatment of threatened and habitual abortion only, since, once the abortion has become inevitable or is in the process of taking place, treatment becomes a matter of emptying the uterus as quickly and as safely as possible.

The problems of treating threatened abortion and habitual abortion seem to be essentially different. In the former instance, efforts are directed at stopping the uterine bleeding and associated cramps, when present. In the latter, one seeks to prevent the various and often quite diverse factors that have contributed to the previous abnormal pregnancy. Thus, the treatment of the one is essentially an emergency procedure, whereas that of the other is, or should be, an elective procedure, preferably begun before conception. Actually, when one examines the results of treatment as shown in the various published series of cases (Table 2), it appears that the same method of treatment may be equally successful whether the case be one of threatened or of habitual abortion. The only difference appears to be the stage in the pregnancy at which the treatment was started and the dosages of therapeutic agents used.

Table 2 presents the data in series of cases of threatened and habitual abortion reported by various authors, including the methods of treatment and the results. It is impossible in such a table to give details of treatment, for which the reader is referred to the original articles. In the cases listed under habitual abortion there had been

two or more successive abortions, so far as could be determined, cases stated as having had only one previous abortion being excluded. Some authors, however, did not give the number of previous abortions, and their cases may or may not have been those of true habitual abortion. The numbers of

Anhydro-hydroxy-progesterone (Pregneninolone — Ciba, Pragnone — Sehering). The oral dosage in threatened abortion is 10 to 100 mg. daily in one or divided doses for a period of three days to several weeks; that in habitual abortion is 10 mg. twice weekly. This synthetic progestational principle is said by Krohn and Harris²² to be one sixth as effective as progesterone. It is not, however, identical in its action on the uterus (Burge and Holloway²³). Progesterone

TABLE 2. Summary of Data on the Treatment of Threatened and Habitual Abortions.

SENIOR AUTHOR	THREATENED ABORTION		HABITUAL ABORTION		TREATMENT
	NO. OF CASES TREATED	NO. (PERCENTAGE) SUCCESSFULLY TREATED	NO. OF CASES TREATED	NO. (PERCENTAGE) SUCCESSFULLY TREATED	
Burge ²⁸ (1941)	3	1 (33)			Anhydro-hydroxy-progesterone
Buxton ²⁹ (1940)			5*	4 (80)	Progesterone
Campbell ³⁰ (1940)			13*	11 (85)	Progesterone

Soule ⁶¹ (1941)	16	12 (75)			Anhydro-hydroxy-progesterone or progesterone, or both, and thyroid
Stahler ⁶² (1941)			14*	13 (93)	Vitamin E (synthetic) and progesterone
Vogt-Möller ⁶³ (1933)			20	17 (85)	Vitamin L (wheat-germ oil)
Vogt-Möller ⁶⁴ (1936)			56	38 (68)	Vitamin L (wheat germ oil)
Watson ⁶⁵ (1936)	15	11 (73)	25*	21 (75)	Vitamin E (wheat-germ oil)

*Stated to have had two or more previous successive abortions.

†Stated to have had two or more previous abortions, but not whether successive.

‡Eight previous successive abortions, and hence worthy of inclusion, even though only a single case.

treated cases in the reports including a statement of two or more successive previous abortions are followed by an asterisk.

The therapeutic agents listed in Table 2 deserve comment, and the following is a brief outline of the dosages and the methods of administration.

is antagonistic to Pituitrin, whereas anhydro-hydroxy-progesterone is not.

Wheat-germ oil (vitamin E). The oral dosage is 30 to 45 cc in the first twenty-four hours in divided doses, and 4 to 6 cc. daily thereafter until the eighth calendar month (Collins³³).

Synthetic vitamin E (Alphatocopherol — Squibb). The oral dosage is up to 30 mg. daily and up to 240 mg. monthly in divided doses.

Thyroid. The oral dosage is 6 to 30 mg. (1/10 to 1/2 gr.) two to three times daily.

Progesterone. Doses varying from 1/25 rabbit unit to 10 mg. have been given intramuscularly. The average dose for bleeding is 2 to 10 mg. Soule,⁹ whereas the prophylactic dosage is 1 mg. every three or four days for a variable length of time but occasionally through the sixth month.

Diethylstilbestrol. The dosage in threatened abortion (Karnaky¹⁰) is 25 mg. injected into the anterior wall of the cervix, followed by 5.5 mg. every fifteen minutes as long as pain persists. When the latter disappears, 10 mg. is given orally every hour for six doses and then 5 mg. every hour for six doses. Following subsidence of pain and bleeding, 10 mg. is given by mouth daily until the eighth month. In habitual abortion, 10 mg. is given in a like manner as soon as pregnancy is diagnosed and is continued until the seventh month.

Lutein. This is an aqueous extract of corpus luteum (Hynson, Westcott and Dunning) whose exact composition is unknown and at present has not been completely bioassayed. Its effective strength is said by Falls¹⁵ to be such that 1 cc. is equivalent to 1/10 unit of progesterone. In threatened abortion, Falls and his collaborators inject 3 cc. intramuscularly every four hours during active bleeding and cramping, in addition to absolute bed rest. After symptoms of bleeding and pain have subsided, 3 cc. is given daily for five to seven days and then 3 cc. twice a week until viability is reached. For habitual abortion, these authors inject 3 cc. intramuscularly twice a week.

Threatened Abortion

It is evident from Table 2 that several hundred cases of threatened abortion have been treated in a variety of ways. There is a total of nine series^{5, 15, 23, 32, 40, 42, 43, 51, 55} containing 15 or more cases in which only one specific therapeutic agent was used. The latter varied from diethylstilbestrol through natural and synthetic vitamin E to preparations of corpus luteum.

These various specific agents may not be quite so diverse in their action on the pregnant uterus as appears at first glance. Thus, the metabolism of the estrogens and that of progesterone are closely correlated, as shown by the work of Smith and Smith.⁵⁶⁻⁵⁸ A practical illustration of this correlation is the method by which Schneider^{49, 50} treats his cases of threatened abortion: estrogen and pregnanediol levels are determined and the patient is given the hormone that is shown to be abnormally low. Also, the role of vitamin E in its essential relation to normal pregnancy is not yet well understood: Stähler and Kaiser,⁵² Stähler and Pehl⁵⁹ and Bach and Winkler¹⁶ cite evidence for the relation between vitamin E (synthetic tocopherols) and progesterone, whereas Shute⁶¹ speaks of the imbalance between vitamin E and estrogens. A relation between vitamin E and iron assimilation by the fetus is indicated by the work of Simmonds, Becker and McCollum.⁶⁰ These workers ascribe fetal death in rats deficient in vitamin E to a crisis in iron assimilation that is obviated by giving vitamin E in adequate amounts at the beginning of pregnancy.

These specific agents for the treatment of threatened abortion are often used in various combinations, either with or without the addition of thyroid. The role played by the latter in pregnancy is not fully understood. That it is important, however,

is shown by the increase in the abortion rate in so-called "goiter areas" (Hamblen,⁶¹ 1943). With the adequate use of thyroid in such areas, there is a reduction in the abortion rate.

Other specific substances, such as the so-called "antihemorrhage" vitamins C and K, have recently been used in the treatment of threatened abortion by Javert and Stander.¹¹ In a high proportion of these authors' cases the use of these substances is predicated on the demonstrably low values of the substances themselves or of their essential end product.

The treatment of threatened abortion is centered on the problem of stopping hemorrhage and quieting the uterus. For this purpose some progestational principle is often used. Hamblen,⁶¹ in a recent review article, thus summarizes the status of this phase of the therapeutic problem:

Numerous reports have cited the efficacy of progestin in preventing abortion. Progestin often has received credit for success when the effects of adjuvant measures, such as thyroid substance, bed rest, limitation of sexual and other activities and so forth, have not been evaluated. We have not been impressed particularly with progesterone therapy in these conditions. Our percentage of successfully treated patients has not been as high as those of some other investigators, although the dosages were comparable or larger. When pregnant women show definite evidence of deficiency in the progestational principles, — that is, decreased pregnanediol values of the urine, — even the most intensive progesterone therapy fails to prevent abortion.

Although apparently patients with low levels of pregnanediol excretion often abort and therapeutic efforts may fail to raise the levels of this substance by progesterone administration, the administration of some potent corpus-luteum preparation, preferably progesterone, seems indicated in cases of threatened abortion with uterine cramps, since this is probably the most effective way of stopping such signs and symptoms if the abortion is not inevitable. Concerning progesterone versus other derivatives of the corpus luteum, Macht⁶² cites evidence that an aqueous extract of the latter, Lutein (Hynson, Westcott and Dunning) is a potent preparation, 1 cc. of which is equivalent to 0.1 mg. of progesterone. It must be realized, however, as Buxton²⁹ states, that there are so many variables in progesterone metabolism and excretion that pregnanediol assays cannot indicate the degree of progestational activity.

Ideally, of course, it would be desirable to know in advance whether or not a threatened abortion is inevitable. Since this is impossible, efforts are necessarily directed at saving the third of spontaneous abortions that theoretically can be saved, even though this entails treating the remainder, which are inevitable in spite of treatment. If it is possible to determine, as does Schneider,^{49, 50} which of the ovarian hormones is low in a case of threatened abortion, the low one should be administered. Otherwise, it seems well to treat the patient by some

form of corpus-luteum preparation, vitamins E, C and K and thyroid, this treatment being correlated with a program of so-called "nutritional adequacy," as advocated by Javert and Stander.¹²

That the treatment of threatened abortion is unsatisfactory at best is indicated by the variety of its causes and the present diversity of its treatment. Elucidation of these complex etiologic factors and evaluation of one or several specific therapeutic agents in various combinations await the study of large series of cases by investigators who will use the combined talents of the obstetrician, the endocrinologist and the embryologic pathologist. Until this time comes, the treatment of threatened abortion and its closely related syndrome, habitual abortion, rests on the physician's practical judgment aided by empiric uses of more or less specific substances whose action is not fully understood at the present time.

Habitual Abortion

The foregoing remarks are applicable in general to the problem of the treatment of habitual abortion. This condition differs from chance abortion in that the same etiologic factor tends to be repeated in two or more successive abortions. Such a recurrent factor is often the same as the chance or isolated factor causing a single abortion.

Treatment should begin prior to conception, because the genesis of many abortions is laid during the time before the first missed menstrual period. The same over-all treatment is indicated as is advocated above for threatened abortion, because of the present lack of more specific therapeutic knowledge. The use of progesterone or some other potent corpus-luteum derivative is indicated before bleeding and cramping begin, because of its effect on the pregestational endometrium and the latter's effect, in turn, on the ovum — even before its implantation.

Vitamin E, judging from the literature, has an important effect on the favorable outcome of pregnancy in cases of habitual abortion — this in spite of the fact that the average human dietary cannot be shown to be deficient in vitamin E. Bacharach,¹³ in 1940, summarized several relatively large series of true habitual abortions reported by other authors and showed that vitamin E apparently supplied the specific factor, so that patients with two, three and four previous abortions had a 75, 73 and 79 per cent chance, respectively, of a successful pregnancy. The rate of spontaneous cure in such cases if untreated, according to Malpas,¹⁴ would have been 62, 28 and 7 per cent, respectively.

In contrast to these relatively hopeful data are the conclusions of the report of the Council on Pharmacy and Chemistry of the American Medical Association,³ also published in 1940, which used some of the same data reviewed by Bacharach.¹³ This report states that vitamin E cannot as yet be accepted owing to lack of convincing evidence,

because the diagnosis of habitual abortion is open to question in these cases, because of the variation in dosage, and because not enough is known about the spontaneous cure rate in habitual abortion. Nevertheless, in my opinion vitamin E should be used because it appears to offer great hope in salvaging pregnancies that would otherwise habitually abort.

CONCLUSIONS

Threatened abortion occurs in at least 16 per cent of all pregnancies.

Spontaneous abortion occurs in approximately 10 per cent of all pregnancies.

Habitual abortion constitutes approximately 4 per cent of all spontaneous abortions.

Approximately 40 per cent of threatened abortions do not abort regardless of the treatment employed.

Approximately 60 per cent of threatened abortions abort if untreated.

On the basis of a series of 1000 cases examined embryologically and pathologically, approximately one third of spontaneous abortions are theoretically capable of being salvaged at the time the patient is first seen by the physician.

In view of the three preceding conclusions, approximately 60 per cent of threatened abortions under adequate treatment may fail to abort.

Threatened abortion should be treated by some potent corpus-luteum preparation or, if estrogens are demonstrably low, by the administration of these substances. These hormones should be supplemented by vitamins E, C and K and thyroid, in conjunction with a program of so-called "nutritional adequacy."

Habitual abortion should be treated in the same manner as is recommended for threatened abortion, except that treatment should begin prior to or coincident with conception.

in case some of my remarks seem to be elementary at times.

"A sixty-five-year-old housewife entered the hospital because of abdominal pain." When one sees a patient or examines a protocol like this, which is essentially the same thing, I think one gets an immediate impression. I make a mental note that the patient was in the decade of life when on the whole carcinoma is most frequent, and that the patient was a woman, and therefore the possibility of disease of the pelvic viscera must be considered later.

If we can believe the history it is perfectly obvious that there was no immediate antecedent history that had anything to do with this attack. It was a sudden, acute abdominal attack. The light lunch obviously had nothing to do with it. She had severe abdominal cramps, which were obviously due to painful peristalsis, and immediate vomiting. What is the significance of these two symptoms? First, of course, by far the most frequent cause of abdominal pain with vomiting and cramps is some form of acute gastroenteritis, gastrointestinal "flu" if you like, or some functional disturbance. In other words, it would, up to that point, explain everything perhaps, and the diagnostician's chief care is to differentiate the functional disturbance of that sort, which is obviously not surgical, and an acute condition in the abdomen of a surgical nature. That is always the thing that should come to the mind of the local physician when he sees such a patient.

As to the bowel movement, it may be presumed that she was somewhat constipated and that the lower colon and rectosigmoid were full of feces when she came in, and with some stimulation of peristalsis she had three formed stools, which means the normal movement of the lower bowel, and the last one semiformed.

The vomiting is interesting. She vomited nine times with distressing retching every time. When the stomach and intestine are affected by a functional disturbance there may not be very much pain. There is apt to be vomiting and diarrhea, but once the intestine is empty that is apt to be the end of it, although the intestinal diarrhea may go on. Here is a woman who nine times had repeated retching and vomiting. We are not told whether the vomitus or the gastric contents contained bile or blood or material suggestive of jejunal contents, but we assume, inasmuch as we are not told these things, that it did not contain anything significant. I think it was one of the Mayo group who once said, among many other wise things, that the stomach was the alarm clock of the physical economy. The stomach is apt to reject its contents, and vomiting to set in, in all sorts of conditions — acute gastritis or any acute condition within the abdomen. As you well know, the emotions may cause vomiting, or it may occur at the beginning of infectious disease or with disturbance of the internal ear or a brain

tumor, and so it goes. In other words vomiting must never be considered as necessarily or even probably indicative of trouble in the stomach, although that is a frequent cause. So my impression here is definite — that this vomiting was of a reflex nature due to some insult to the peritoneum of the abdominal viscera below the stomach and probably had nothing at all to do with the stomach.

Evidently this patient was not used to gritting her teeth, and waiting and suffering in silence. She sent for a doctor quite promptly. She undoubtedly was an intelligent person. From here on there is mentioned a number of times the type and degree of peristalsis noted. Some of the gentlemen here may have devoted themselves to the study of peristalsis. Personally, I do not believe that much significance can be attached to the determination of peristalsis, except very broadly; if we examine the abdomen and find absent peristalsis we may assume that in all probability the situation of paralytic ileus exists. The prototype and usual cause is peritonitis, unless there be some toxic cause. The other is extreme peristalsis with a tinkling sound, which we hear in the early stages of acute mechanical obstruction. Between these extremes one cannot tell much about the significance of peristalsis, but evidently the group that studied this case did think there was a good deal in it, very likely something I do not realize.

Of course the degree of tenderness is extremely important but there was no localized tenderness, and no spasm, and therefore, we can confidently rule out peritonitis. Certainly we can rule out acute perforative peritonitis. Acute perforation of a hollow viscus would give exquisite localized pain, exquisite localized tenderness and boardlike spasm and rigidity — a very different thing from what we have here. The question arises, Of what significance was this tenderness? Was there any peritoneal insult? Hardly. I simply remind you of the fact that if any of you have happened to be unfortunate enough to be seasick, and perhaps have vomited nine times, with retching, you know that the belly becomes quite tender, so I do not believe that this tenderness was important; but we can say that there was no perforative peritonitis. "Abdominal tenderness became more marked, so that any but the most superficial abdominal palpation caused marked pain referred to the midepigastrium." Again we should like to know how much tenderness there was, but again we may assume that there was no marked spasm related to it. So that it does not seem to me significant. The reference of the pain to the epigastrium is extremely interesting, of course, and must be of great importance. Anatomically speaking, we think of the organs that are situated in the epigastrium shall not bore you with enumeration — the stomach, pylorus, duodenum and forth cover so

remember that the pancreas is situated there. It is an organ that must always be considered in any acute abdominal situation. The symptoms of acute pancreatitis, the typical ones, are very characteristic; yet many a case of pancreatitis is quite obscure from a diagnostic point of view. So let us remember the pancreas.

What is the likeliest cause of the pain in the epigastrium? As we know, pain due to spasm of the small intestine as contrasted with painful peristalsis of the large intestine, is apt to be referred to the region above the umbilicus, and in the large intestine is apt to be referred to the hypogastrium, below the umbilicus, and that, as you well know, is because the sympathetic pathways from the intestine are related to certain metameres of the body—thus pain in the small intestine is associated with pain sensations referred to the distribution of the seventh, eighth, ninth and tenth dorsal nerves in the epigastrium. That is a general statement and a useful one, but of course it must be mentioned that it is frequently violated.

"There was no pain in the back, shoulder or scapula." That statement refers undoubtedly to the absence of symptoms that might have been caused by injury to the phrenic area. Also, absence of pain in the back suggests that the gall bladder was not involved.

The vague mass that was palpable we must take as something that could not be identified; its actual existence was not certain.

This patient had a very discriminating and keen physician to attend her. The notes that he makes here are those of an experienced man who has seen this type of case. One-sixth of a grain of morphine after he made the examination was necessary, and the proper treatment. One-sixth of a grain could hardly mask any important symptoms. We know that she got through the night very well indeed. As to the propriety of having her go through the night, if I were a beneficent dictator, I should advise that any patient with acute abdominal pain and vomiting in which there is any doubt whether something more than a functional disturbance exists should go to a hospital. But perhaps that is too much to expect, and certainly the course of this case justified her being kept where she was. We surgeons know that the possibilities of acute abdominal pain and vomiting are so great that we should like to have had her under hospital observation where interferences could have been carried out if necessary. The night is quite long for a patient with acute abdominal pain.

"She had one small, liquid, pinkish bowel movement." That is extremely interesting and important; undoubtedly the color was due to blood. Something caused bleeding into the gastrointestinal tract. The most probable thing would be an ulcer. We do not know whether she had previously had occult blood in the stools, but here definite gross

blood appeared, which suggests ulceration. But bear in mind that it also suggests interference with the circulation in the intestine somewhere, or strangulation, or acute passive congestion, with a little leakage into the intestinal loop. Indeed, that is extremely important.

It is perfectly evident that the doctor became convinced that the disturbance in the upper abdomen should be under surgical observation.

It is interesting that the patient had had anemia for years and had had liver therapy, but it is obvious that she did not have pernicious anemia. It is just possible that she had had for years some lesion in the bowel that had been leaking a little bit, not causing enough bleeding to be observed but enough to cause anemia; possibly there was a connection between that and the present condition.

This patient had had a laparotomy and uterine suspension thirty-three years before entry. I should like to call to your attention that whenever the surgeon sees an abdominal scar he attributes a great deal of importance to it. In the first place, whatever the condition was for which she was operated on, it may have recurred, and one particularly thinks of carcinoma. The second point is that there may be a condition in the abdominal wound itself that may be the cause of the present symptoms. Of course I refer to a weakened wound with interstitial hernia, which is evident to the examiner. The third point, and in this case much the most significant, is that the operation may have resulted in adhesions, which cause some sort of band that may be the cause of the symptoms. Thirty-three years is a long time for that. It would depend a great deal on the character of the operation. It says "uterine suspension," I suppose of the modified Watkins's type. It might have been an attachment of the fundus of the uterus to the abdominal wall, which makes a long pulled-out band that is just the kind of thing which loops of small intestine insinuate themselves around and give obstructive symptoms, but I am surprised that that could have occurred so long after the operation. It is possible that a hysterectomy was done at that time. Hysterectomy in the hands of the average surgeon in those days was not the same as it is now. There was no satisfactory effort made to repair the pelvic floor, and there was quite a long area, running from the pelvic brim across to the cervix, where adhesions could easily form and produce acute intestinal obstruction, owing to strangulation by a band due to the adhesions.

The physical examination does not mention whether there was vomiting after the initial nine spells, which would be interesting to know. There was little real spasm. Again we have no suggestion of peritonitis, and I call your attention to the fact that the typical syndrome of acute, complete, intestinal obstruction was absent, that is to say, pain, obstipation, distention and vomiting. There

was pain, and there had been vomiting, but there was no persistent obstipation or distention. So we do not have the inevitable syndrome of symptoms that necessitate a diagnosis of acute intestinal obstruction. Still there may be intestinal obstruction because all these elements of the syndrome may not be present.

"Peristalsis was almost entirely absent." The intestine got tired trying to pass things along, and that suggests a little bit the possibility of peritonitis. "Palpation anywhere in the abdomen gave rise to pain in the epigastrium." That would not be so in pancreatitis; as a rule, palpation would have to be more or less over the region of the pancreas if the pain were due to pancreatitis. This does suggest to me, however, that intestinal coils on palpation of the abdomen were pushed about from one part to the other, making traction on the root of the mesentery, which would cause pain in the epigastrium. There was no definite spasm or tenderness over the abdomen, and with acute pancreatitis there should be definite tenderness and spasm, although not the boardlike rigidity of the perforated viscus. No vaginal or rectal examination is mentioned. Of course they were done, and we may assume that they were negative.

"Examination of the blood showed a white-cell count of 17,300, with 86 per cent neutrophils." That is an indeterminate degree of leukocytosis. I call your attention to the fact that there may be a certain amount of hemoconcentration, which increases the white-cell count to a certain extent.

Then we come to the x-ray examination, and we might glance at the films. The small intestine normally contains little if any gas. It is almost always completely filled with fluid. In obstruction there is gas, and we must be able to differentiate small intestine and large intestine. There you see quite plainly the valvulae conniventes close together—so different from the haustra of the large intestine. The diameter of the bowel is distinctly increased, not markedly so. I am not sure whether this other loop is small intestine or large intestine. That may be normal large intestine. The one loop of distended small intestine almost certainly means obstruction. Another point is that there is no gas under the diaphragm, which, if this were taken in the standing position, would be evidence against perforation.

An operation was performed two hours after admission. I call your attention to the fact that probably we cannot, from this printed protocol, get a satisfactory idea of the patient's condition. From it I learn that she had a good night and came in without having had further vomiting, that the blood pressure fell a little and that the white-cell count was slightly elevated; the picture as given is not that of a very sick woman. The history, however, is extremely significant and it is perfectly clear that the experienced men who saw her made

up their minds that it was an acute condition of a surgical nature. Let me remind you—I have it underlined here—that the most important factor was not the exact condition existing here, but whether it was a surgical emergency; in other words, whether there was a condition that might have been treated expectantly along medical lines, or whether she had to be explored. I am not going to enumerate all the causes of acute episodes like this in the abdomen with symptoms of at least partial obstruction, perhaps complete obstruction, but I am going to bring to your attention, of course, the question of Meckel's diverticulum. It must be remembered that, that being a congenital anomaly, it would be rather strange to have a Meckel's diverticulum become adherent late in life and form a band that became strangulated. If attached to the umbilicus it would have caused symptoms earlier. It is still a possibility. Another condition that I shall rule out from lack of antecedent history and from lack of x-ray confirmation is obstruction from a gallstone that had ulcerated into the intestine, although, let me say immediately, a large cholesterol gallstone can ulcerate through to the duodenum and a phlegmatic patient often gives no antecedent history, and the x-ray may not show it.

Then there is volvulus, but that does not appeal to me. There is intussusception. Intussusception, of course, is almost practically confined, except for a few cases that have been described, to the period of life before five years; most of them occur before one year of age. Intussusception of the terminal ileum into the cecum is the usual rule. But there is a form occurring in the adult that usually appears in the small intestine and is invariably due to the presence of a tumor, and in my experience usually a nonmalignant tumor, a lipoma or fibromyoma of the small intestine. The tumor gets caught in a peristaltic wave and gets drawn into the distal bowel; it is pulled along by peristalsis and forms a true intussusception that can relieve itself readily and may occur again and again. The first attack may be significant. If that occurred here it would have caused obstruction accompanied by acute passive congestion, with leakage of blood into the bowel. Moreover, we might link it up with the moderate degree of anemia for a considerable period, because such a tumor may have given rise to leakage from time to time, although I do not believe that that is important.

Pancreatitis, I am going to remind you, is always a possibility, but the lack of marked tenderness in the epigastrium and pain in the back, the very sudden onset, which is not characteristic of pancreatitis, and the failure to get any antecedent history to suggest it practically rule out pancreatitis.

I see no cause for considering thrombosis. There is nothing to suggest arterial mesenteric em

There is another point to stress, and I am perfectly certain that it was done here, and that is that one never fails, when confronted with a case like this, to examine with the greatest of care the region of inguinal and femoral hernias. In a woman, femoral hernia, especially in an adipose woman, may be so small as to be indistinguishable. The pain of hernia may not be referred to the site of the hernia but to the epigastrium because of the pull on the mesentery of the bowel which is attached there. I know of two cases in which, because of the combination of an ultramodest patient and a diffident physician, the site of femoral hernia was not examined and therefore operation was delayed, with resulting exitus.

So far as operation is concerned, the anesthesia was probably spinal, although some people think that the inhibition of the sympathetic nerves leading to increased peristalsis produced by spinal anesthesia might be harmful in intestinal obstruction. Local anesthesia and gas would be fairly satisfactory. If a general anesthetic were used, especially ether, we would surely pass a stomach tube first and keep it in place during anesthesia. There is nothing more fatal than the vomiting that occurs under ether anesthesia in cases of intestinal obstruction. I presume a paramedian incision was made, starting at the umbilicus.

DR. BENJAMIN CASTLEMAN: Would you like to state your first choice?

DR. CHEEVER: Intussusception due to tumor, probably benign, of the jejunum.

DR. ARTHUR W. ALLEN: I should like to compliment Dr. Cheever on his masterly discussion of this patient. He has covered the situation with great thoroughness.

This patient happened to be the widow of a physician who was a colleague of mine in World War I. I have known her a good many years. I had never seen her professionally, but I had known that she had a hard time keeping a normal weight and that she had a good deal of gastrointestinal difficulty requiring special diet—iron, liver and so forth.

Dr. John T. Quinby is the man who saw her first and realized that she was an ill woman. He talked to me about her on the telephone about seven o'clock in the evening, and I suggested that it would be all right to give her a little relief with 1/6 gr. of morphine and that if she did not get better from the "ptomaine poisoning" which she was sure she had, I would come in to see her. I did see her about nine-thirty that night and could not, for the life of me, bring myself to think that she represented an acute abdominal emergency. The lack of high-pitched peristalsis, the fact that the vomitus at that time was nothing but undigested food, with no evidence of intestinal contents, the repeated stools, the reference of her pain to the epigastrium, with actually more tenderness in the

epigastrium than elsewhere, made me believe that my second choice, after acute gastrointestinal upset, was pancreatitis.

In defense of Dr. Quinby I might say that we tried to get her into the hospital, but there were no beds; so the best we could do was to get a nurse and Dr. Quinby stayed with the patient through the night, keeping his eye on her. I thought that was as adequate as having her in the hospital, where we should undoubtedly have kept her under observation much the same way.

The next morning, at six o'clock, it was obvious to us that she was still ill, and finally the Admitting Office decided we could have a bed in the Emergency Ward. We got her in and immediately had this x-ray film made, which, of course, clinched the diagnosis. But before this film was made and before Dr. Quinby told me there was blood in the stool that she passed during the night, I thought that this woman had a medical disease, not a surgical belly; that is how close we came to missing it.

CLINICAL DIAGNOSIS

Intestinal obstruction, small bowel.

DR. CHEEVER'S DIAGNOSES

Intestinal obstruction.

Intussusception due to tumor, probably benign, of jejunum.

ANATOMICAL DIAGNOSES

Intestinal obstruction.

Infarction of small intestine due to adhesive band.

PATHOLOGICAL DISCUSSION

DR. ALLEN: At operation we found intestinal obstruction due to a band that was running from the region of the right upper quadrant across the terminal ileum, very close to the cecum, but far enough away to allow the entire mesentery of the small bowel to rotate around it. There was an enormous amount of dead terminal ileum due to thrombosis of the vessels that had become occluded mechanically by the torsion. The band ran down to the region of the old suspension—a very small band, not more than 2 mm. in diameter.

I was confronted with the problem of how much small intestine she could spare. She had had a hard time getting on with what she had been born with. So I started at the terminal ileum and removed the bowel up to a point where I thought there was some chance for the rest of it to come back, taking out 71 cm., which is an appreciable length. We then observed the other 100 cm. or so of small bowel that was involved, which made a fairly satisfactory return. I had to gamble that complete circulation would be restored to the latter segment, since I knew that, had I taken it out, she would certainly

have suffered from a deficiency state. Anastomosis between the ileum and the cecum was done, and she made a pleasant and uneventful convalescence.

DR. CHEEVER: There are two things I should like to say. The first is to emphasize the impossibility, in a case of intestinal obstruction, of deciding, with any certainty, whether or not strangulation exists. I think Dr. Allen will bear me out in this — until the matter has reached the final stage there are certain things one cannot be sure of. The other thing, which I say with the utmost sincerity, is that this patient was fortunate that she fell into the hands of someone who knew what he was doing. When I learned that it was a good friend of mine, I was much pleased, but to spare his blushes I should not say so.

CASE 30262

PRESENTATION OF CASE

First admission. A sixty-three-year-old watchman entered the hospital because of gnawing abdominal pain.

The patient had been in apparent good health until nine months before entry, when he noticed frequent attacks of heartburn, which came on a few hours after eating and were relieved by soda and food. Three months before entry he was seen in the Out Patient Department, where a gastrointestinal series showed a small crater in the pylorus. He was placed on a six-meal bland diet and tincture of belladonna. In the course of the next two months he experienced considerable relief, and x-ray films showed definite evidence of healing. A gastric analysis showed no free acid in the fasting specimen and only 38 units after histamine injection. During the month prior to admission the patient had recurrence of the heartburn and lack of appetite.

Physical examination on admission showed a well-developed, well-nourished, but pale man. The heart, lungs and abdomen were normal.

The blood pressure was 120 systolic, 75 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood showed a red-cell count of 4,600,000, with 12 gm. of hemoglobin. The white-cell count was 8500, with 67 per cent neutrophils. The urine was normal. A blood Hinton test was negative. The stools were guaiac negative. A gastrointestinal series (three and a half months after the first studies) showed a large crater above the angle of the stomach, slightly toward the anterior wall. Below this point there appeared to be one or more smaller craters.

The patient was given a gastric diet and atropine. After two weeks on this regime repeat x-ray studies showed the large ulcer to be approximately the same size as it was in the previous examination. Accord-

ingly, a subtotal gastrectomy and posterior antiperistaltic Hofmeister anastomosis were performed. The pathological examination showed peptic ulcers without any evidence of malignant disease. Postoperatively the patient did well, and he was discharged home on the thirty-seventh hospital day.

Final admission (one month later). Following discharge the patient remained well until six days before readmission, when he had two chills without fever, felt ill and went to bed. Two days later he vomited whitish, questionably bile-stained material. About that time he noted the onset of jaundice. Subsequently, the stools became clay colored, and the urine dark. At no time did he experience pain or have fever. He had had no previous jaundice.

Physical examination showed a moderate degree of jaundice. There were tenderness and voluntary spasm in the right upper quadrant. On deep inspiration the liver edge was palpable 5 cm. below the costal margin in the anterior axillary line. Examination was otherwise negative.

The blood pressure was 95 systolic, 60 diastolic. The temperature was 98.6°F., the pulse 85, and the respirations 20.

Examination of the blood showed a white-cell count of 5200. The hemoglobin was 82 per cent. The stools were clay-colored, with brown streaking and a ++ guaiac test. The urine was normal. The blood nonprotein nitrogen was 35 mg., and the protein 5.2 gm. per 100 cc. The blood chloride was 98 milliequiv. per liter. The van den Bergh was 10.3 mg. direct, and 14.6 mg. indirect. A film taken after one swallow of barium showed the barium to pass readily through the stoma into the nondilated efferent loop. The spleen was slightly enlarged. A film of the abdomen was normal.

The patient was given intravenous fluids. The jaundice increased. In the course of the next six days, the direct van den Bergh rose to 18.6 mg. per 100 cc., and the indirect to 24.4 mg. A bromsulfalein test revealed 100 per cent retention.

On the sixth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. WYMAN RICHARDSON: I have no idea what a "posterior antiperistaltic Hofmeister anastomosis" is. It might be important in this case. Presumably this patient had transfusions at that time, but I want to know definitely whether he did. That is a fair question, I believe.

DR. BENJAMIN CASTLEMAN: He was given two transfusions.

DR. RICHARDSON: That is enough.

I take it that the two chills he had were real, otherwise they would not be put in the abstract.

I should also like to know whether he had ever had any fever. I should prefer that he had fever during the second admission.

DR. CASTLEMAN: Here is the chart.

DR. RICHARDSON: He had a temperature of 101°F . by rectum for one day.

"The van den Bergh was 10.3 mg. direct, and 14.6 mg. indirect." As I have said many times before, the latter is misleading. The 14.6 mg. is the total bilirubin. One has to subtract 10.3 from 14.6 to get what we ordinarily consider the indirect. In other words, the van den Bergh test showed that two thirds the bilirubin was demonstrated by the direct method, which of course is suggestive evidence of obstructive jaundice. The bromsulfalein test showed 100 per cent retention, which anyone would have predicted in a patient with this degree of jaundice. There is no point in doing this determination in the presence of severe jaundice.

I should like to make a comment or two about the laboratory findings before I go on to differential diagnosis. The first is about the blood. In this case a blood smear would have been helpful. If it had shown some abnormal lymphocytes, suggesting mononucleosis, I do not believe that this would have been detected on the surgical service and probably not always on the medical service. This finding would be of some differential importance, suggesting infectious hepatitis. Another thing I want to comment on is the total protein of 5.2 gm. If that was an accurate determination it is definitely low.

In regard to differential diagnosis, I am going to take up only three possibilities: silent stone in the common duct; adhesions or distortion due to ulcer or possibly postoperative inflammation resulting in obstruction to the common duct; and acute infectious hepatitis.

I do not believe this patient had stones. My chief reason for this statement is that the combination of gallstones and ulcer in the same patient is almost unheard of. If anyone has heard of that combination I should be glad to have him speak up. It is a striking thing that the ulcer habitus and the gallstone habitus are quite different, and I do not believe that I have ever seen the two diseases in the same patient. There are other features about the case that are against stone. He had had no previous attacks of pain, but of course one can never rule out stone on that basis.

Now what about the question of jaundice due to ulcer? One can have jaundice due to ulcer in the region of the ampulla, or one might have a considerable inflammatory reaction around an ulcer that was near the ampulla, but one would not get it from ulcer in or above the pylorus. There is no mention or suggestion of ulcer below the pylorus, so I think that that can be ruled out.

That brings up the question of an inflammatory postoperative reaction. Just why there should have been a considerable amount of inflammatory reaction in the region of the common duct, I am not sure; but it would seem possible as a result of the rather complicated gastric surgery that went on. The sudden onset with chills is very much opposed

to that diagnosis, however. I should expect a gradual onset with jaundice and nothing else — a rather slow progression of severe and intense jaundice after a period of a good many weeks. This was rather sudden in onset, with chills and possibly fever and then severe jaundice, an apparent rapid increase in the size of the liver and possibly splenomegaly by x-ray examination.

I therefore think that the evidence is in favor of infectious hepatitis. If so, what was the cause of it? One would have at least to bring up the possibility that it was caused by the transfusion that was received at the previous operation. My diagnosis is infectious hepatitis possibly secondary to transfusion.

I want to say one more thing, which is certainly true whether I am right or wrong about the diagnosis. There was no particular hurry about operating on this patient. It seems to me that he was operated on too quickly. He should have been kept in bed and watched for a while. Now that we know that we can protect against prothrombin lack, there is not too great a risk. It is less of a risk to be sure that one does not operate on a patient with a sick liver due to hepatitis.

DR. CASTLEMAN: How do you tie up the transfusion with the infectious hepatitis?

DR. RICHARDSON: I was thinking of the modern theory that transfusions from donors who have had jaundice due to hepatitis within a year may be able to transmit the disease to the recipient. There have been some deaths. I believe that it has occurred in all situations involving the injection of human serum. The thought is that the disease is due to a virus.

DR. EARLE M. CHAPMAN: I want to comment on Dr. Richardson's second possibility — a postoperative inflammation about the common duct or head of the pancreas — to explain this man's jaundice. When visiting on the West Medical Service recently I saw four patients with the same pattern of jaundice following surgery for duodenal ulcer, and yet the surgeons insisted that there was no relation between the two. Two of these patients recovered gradually. The chief finding in both was marked tenderness in the epigastrium, suggesting an inflammatory reaction.

CLINICAL DIAGNOSIS

Obstructive jaundice.

DR. RICHARDSON'S DIAGNOSIS

Infectious hepatitis, possibly due to transfusion.

ANATOMICAL DIAGNOSES

Intrahepatic cholangitic biliary cirrhosis.

Acute hemorrhagic pancreatitis, with fat necrosis.

Icterus.

Bile neph.

Operation: subtotal gastrectomy with posterior gastrojejunostomy.

Bronchopneumonia, diffuse.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: At operation the surgeon found the peritoneal cavity remarkably free of adhesions.

present at operation ten days before because it would have been easily seen. The manipulation of the gall bladder at operation possibly forced some bile into the pancreatic duct, thus producing the pancreatitis.

Microscopically the liver presented a very unusual process. There was widespread parenchymal

FIGURE 1. Photomicrograph of Liver, Showing Widespread Liver-Cell Damage.

There was a small amount of bile-stained fluid. There was no dilatation of the duodenum or of the afferent loop. The pancreas was normal in size and consistence. By pressure on the gall bladder he was able to empty it into the duodenum and to aspirate thin greenish bile from an inlying nasal tube. He palpated the entire common duct and found no evidence of stone, tumor or other obstruction. The liver was yellowish-green, tense and firm. Since no obstruction was found, nothing further was done.

Following operation the patient continued to do poorly, became drowsy and disoriented and died on the eleventh postoperative day.

The autopsy showed a normal-sized liver, which was definitely green and slightly firmer than normal. The gall bladder appeared normal. The common duct was perhaps slightly thickened, but normal in size, patent and free from stones. In the region of the head of the pancreas we found a mass measuring 8 cm. in diameter; this was a bit fluctuant and, when cut into, appeared to be an acute hemorrhagic affair. Scattered all over the surface were areas of fat necrosis. There is no question that this was acute pancreatitis. This mass could not have been

destruction involving from half to two-thirds of each liver lobule, which was replaced by granulation tissue infiltrated with lymphocytes and large numbers of polymorphonuclear cells (Fig. 1). There was bile stasis in the tiny bile canaliculi, which were tremendously distended and filled with so-called "bile thrombi" (Fig. 2). This is somewhat similar to the appearance that one sees with an extrahepatic obstructive biliary type of cirrhosis. In this case we were unable to find any extrahepatic biliary obstruction. Karsner,* in a recent review of the literature on hepatic cirrhosis, has used the term "intrahepatic cholangitic biliary cirrhosis," a diagnosis that I believe can be applied to this case. It is an intrahepatic obstructive and infectious process. The lesion, if we go back to when the patient had his first chill, was about twenty-three or twenty-four days old, and microscopically the picture is consistent with that age. One might ask, What is the relation between the liver disease and the acute pancreatitis? Of course, if the acute pancreatitis had occurred first we might assume that it had ob-

RH TYPING SERUM

Rh typing serum is now available for all who need it. This should be welcome news to the obstetrician and to the physician or surgeon administering transfusions, who appreciate the importance of this new blood type and have been concerned because of the lack of diagnostic serum. For the doctor who is not aware of the dangers of Rh incompatibility, the letter regarding the practical aspects of this subject, published elsewhere in this issue of the *Journal*, should be informative.

Except for the important obstetric complications, the sequelae resulting from the repeated trans-

fusions of Rh- recipients with Rh+ blood are obviously of greater concern to physicians in the armed forces than to those in civilian practice. For the former often uses multiple transfusions in the treatment of hemorrhage, shock, blast or burn injury, or chronic infection, and the one man in seven who is Rh- deserves the protection that is offered by this special typing of blood.

The early and, until-recently, the chief handicap to differentiation of Rh+ and Rh- red cells was the scarcity of potent, rapidly active serum. The supply of such material was dependent on the identification of high-titered anti-Rh agglutinins in the blood of the rare woman who built up these antibodies during and maintained them after the birth of one or more infants with erythroblastosis fetalis. Statistically, such an event occurs about once in more than 5000 deliveries. Even if such women were willing and able to donate a pint of blood frequently, the supply of anti-Rh serum from this source alone would fall far short of meeting the usual demand of civilian hospitals and the expanded needs of military establishments. It was therefore necessary to develop a method whereby larger amounts of Rh typing serum are available for immediate use. This project is explained in the letter referred to above, and co-operation of all physicians will ensure its success, thus benefiting chiefly the members of the armed forces at the moment, and everyone after the present emergency passes.

After the war it seems likely that Rh typing will assume even greater significance than it does at present. Certainly, whole blood and resuspended red cells will be readily available and will probably be used freely. The Rh- men returning to civilian life who received one or more transfusions of whole blood during the war may have developed an appreciable titer of Rh agglutinins if Rh+ blood was used, and on being again transfused, severe hemolytic reactions may occur following the injection of Rh+ red cells. Furthermore, the current civilian needs for Rh typing will not diminish. For these reasons, proper Rh typing serum will be required in abundance. The present project offers promise of meeting the need.

THE "OFFENSIVE" ODOR OF GARLIC AND ONIONS

A few years ago the American medical profession was greatly amused, if not much enlightened, by two articles concerning garlic breath that appeared in the *Journal of the American Medical Association*.^{1,2} A recent issue of the *American Review of Soviet Medicine*³ calls attention to a series of scientific investigations on the possible beneficial effects of the vapors of these alliaceous plants when used as bactericides or as phytoncides (plant bactericides).

The therapeutic possibilities of garlic have, in the past, been studied and utilized to a varying degree even in this country and in Great Britain. It has been used in the treatment of infectious diseases such as pneumonia,⁴ as an antihelminthic⁵ and in the treatment of hypertension.⁶ Observations have been made on the bactericidal effect of garlic and onions in vitro against many bacteria,⁷ including *Mycobacterium leprae*.⁸ A systematic study was also reported on the physiologic effects of garlic and of derived substances.⁹ Some of these were found to be highly toxic, whereas others, which are noxious for bacteria or other parasites, are apparently nontoxic and thus have therapeutic possibilities.

The Soviet investigators summarized the results of many experiments concerning the phytoncidal activity of alliaceous plants. They found that extremely small amounts of a paste of freshly macerated onion, garlic or similar plants emit enough phytoncide to kill all exposed unicellular organisms within one to five minutes. They found no protozoa that were resistant to the phytoncides of garlic or onions. They also demonstrated that free-living infusoria and certain flagellates are affected. In certain paramecia, they noted first an apparent stimulation of motility, followed by specific morphologic changes that continued after all motility had ceased. Other investigations indicated that large concentrations of these vapors introduced into animals by inhalation caused a rather pronounced stimulation of the wandering cells of the connective tissue but no parenchymatous changes in the organs.

The Russian workers went on farther, applying these plant phytoncides in the treatment of in-

fected wounds. Gratifying results were obtained in many cases of delayed healing, particularly amputated stumps in which there was considerable purulent inflammation of the wound. Regeneration of tissues proceeded rapidly in spite of the frequent dressings required by the treatment. All the clinical results, however, were not favorable. In some cases, epithelization stopped suddenly after a few treatments, and in others, there was an increase in granulation tissue and a lack of epithelization in other parts of the wound.

These findings may serve to intensify the interest in finding new remedial agents derived from living plants, including micro-organisms. The practical results are well exemplified in the great advances that followed the discovery of gramicidin and penicillin. The finding of new and effective substances leads, in turn, to identification of the active principles with a view to defining the chemical structure of the agents responsible for the various beneficial activities, as well as those associated with toxic properties. Eventually this should lead to synthesis of similar or related chemical compounds having the optimum therapeutic activity and the least injurious effects.

CORRESPONDENCE

RH TYPING SERUM

To the Editor: In 1940, Landsteiner and Wiener discovered a new antigenic substance in the blood—the Rh factor—present in 87 per cent of the white population and absent in 13 per cent. At first it was thought to have no practical or clinical importance. It was soon demonstrated by Levine and by Wiener, however, that Rh- persons (those lacking this Rh agglutinin) might, under certain circumstances, develop immune antibodies against the Rh factor and suffer serious consequences from the action of such anti-Rh agglutinins.

Abundant evidence has been collected by now to show that anti-Rh agglutinins may be developed in Rh- males and females as the result of one or more transfusions with Rh+ blood, and in women by repeated pregnancies involving an Rh+ fetus (this blood type being inherited as a dominant characteristic from the father).

Recognized intragroup transfusion reactions due to Rh incompatibility have apparently been quite rare in civilian practice. This does not imply that Rh- persons who receive Rh+ blood fail to develop antibodies. On the contrary, data from the Blood Grouping Laboratory in Boston suggest that many such recipients develop weak agglutinins. Subsequent transfusion reactions are fairly mild unless numerous transfusions are given and agglutinins increase in strength. Probably the most important reason for the failure to note a higher percentage of hemolytic transfusion reactions of this type is that multiple transfusions are the exception in civilian practice, more than 95 per cent of the transfusions being single infusions of blood. In contrast to this, in the treatment of members of the armed forces, multiple transfusions are exceedingly common, and therefore transfusion reactions in the 13 per cent of the population who are Rh- are quite likely to become more frequent and severe, thus interfering with benefit from the procedure, with speed of convalescence and even with eventual recovery. This has been borne out by the published statistics.

Because of the increasing availability of plasma and whole blood, and the attempt to diminish maternal mortality due to hemorrhage and puerperal sepsis, transfusions are now given to patients on obstetric services much oftener than in days past. In contrast to the experience with medical or surgical cases, a first transfusion of Rh+ blood to an Rh- mother who has been sensitized by pregnancy with an Rh+ fetus may be followed by a fatal reaction. Also an Rh- woman of child-bearing age, given Rh+ blood, will be sensitized and will develop anti-Rh agglutinins; if she then has a pregnancy involving an Rh+ fetus the child will develop erythroblastosis, often of the severest type.

To sum up the accumulated facts, it may be stated that Rh incompatibility is of practical importance under the following conditions:

(1) Rh- recipients, men and nonpregnant women, who receive repeated transfusions of Rh+ blood may have intragroup hemolytic transfusion reactions. Such reactions do not occur following the first transfusion; but after a suitable interval for the development of antibodies, further transfusions produce signs of increasing hemolytic reaction with jaundice, anemia and, finally, anuria.

(2) Rh infants born to mothers who have anti-Rh agglutinins may show varying degrees of hemolytic anemia of the newborn, or erythroblastosis fetalis. The severer forms are characterized by late fetal death with congenital hydrops and icterus gravis. In this situation, Rh typing of the mother, father, and child is of diagnostic value, and demonstration of anti-Rh agglutinins in the mother may fix an otherwise questionable diagnosis.

(3) Serious and even fatal hemolytic transfusion reactions may result from the first transfusion in Rh- women who have been sensitized and have developed anti-Rh agglutinins through pregnancies.

(4) The use of Rh+ blood for transfusion of Rh- women, even for the first time, may initiate the formation of anti-Rh agglutinins and produce erythroblastosis of a severe or fatal form in their Rh+ offspring.

For the above reasons, it has become apparent that Rh typing should be carried out in the following persons:

(1) Recipients of whole blood or of resuspended red cells, especially if multiple transfusions are contemplated, in order to avoid giving an Rh- patient Rh+ blood. It is most important to type recipients of multiple transfusions or persons having a history of previous transfusions. Donors and stored blood should also be typed for the Rh agglutino-gen so that suitable blood is available for Rh- patients.

(2) Any woman whose history suggests the possibility of erythroblastosis—either by one or more stillbirths or infants born with hydrops, jaundice or anemia—before even a first transfusion is given, since a fatal reaction may occur.

(3) Women of child-bearing age before transfusion, since Rh- women given Rh+ blood may be so sensitized that future pregnancies will result in dead or damaged infants.

(4) Babies born with jaundice and anemia, in order that their recovery may be facilitated by transfusion with Rh- blood.

The military services require Rh typing serum even more urgently than do the civilian hospitals, since multiple transfusions are so much commoner in military institutions, and also because obstetric services are expanding in military establishments. It is necessary to have such serum not only for the typing of recipients, but also for the typing of prospective donors, either for Rh- patients or for a donors' list for banked blood for emergency use. The most serious difficulty in this connection has been the relative paucity of available serum. The reasons for this are threefold:

(1) Experimental or animal serum is difficult to produce and gives agglutinations that are unreliable or difficult to read by the average technician.

(2) High-titered serum of human origin occurs chiefly in women recently delivered of erythroblastotic infants and even here it is found in only 1 of 20 such women, 1 in 4000 deliveries.

(3) Such high-titered serum may be extremely specific (70 per cent instead of 87 per cent positive reaction) and therefore may not be useful for general Rh testing. This makes the occurrence of high-titered useful serum about 1 in 6000 deliveries.

For these reasons, other means of increasing the supply of Rh typing material seemed required. It had been noted that low-titered anti-Rh serums were found ten times as frequently as high-titered serums. This material, however, was not safe for general laboratory use because the tests obtained were not clear cut and many negative results occurred with known Rh+ cells. Through the co-operation of the Department of Physical Chemistry of the Harvard Medical School such low-titered serum was concentrated into a globulin fraction yielding good typing results. This opened the possibility of utilizing the more abundant supply of serum containing low-titered Rh agglutinins and thereby possibly meeting the need for Rh typing material.

Accordingly, a project was started under contract from the Committee on Medical Research of the Office of Scientific Research and Development for the collection and preparation of Rh typing serum. During the past six months, meetings have been arranged with obstetricians, pediatricians and clinical pathologists in all the large medical centers, and the facts regarding the need for Rh typing serum have been presented. It has been suggested that they send a few cubic centimeters of blood from any patient known to them who have had a baby with erythroblastosis or possible erythroblastosis (including late fetal death of undiagnosed cause) delivered within the last two years. If the serum, by *in vitro* tests, shows a useful amount of anti-Rh agglutinin, the physician is notified and requested to obtain from the patient 100 to 500 cubic centimeters of blood which is to be shipped promptly. Such material is pooled for concentration of the anti-Rh agglutinin, and a useful typing globulin is produced. Seventy per cent of the resulting serum is set aside for use by the military services, and 30 per cent is credited to the hospital or physician contributing to this enterprise. Such a credit can be drawn on immediately in the form of standard Rh typing serum, so that any hospital or laboratory may have its own material without delay. Special pre-addressed containers and test tubes are being sent to all physicians and hospitals co-operating in this project so that shipment of specimens may be expedited. Also collecting bottles and pre-addressed containers for sending blood serum via air express, collect, are obtainable on request.

Only through such a co-operative enterprise for obtaining large amounts of Rh typing serum does it seem possible to meet the urgent and increasing needs of the military force as more whole blood is being used; also by this means it is hoped to supply the immediate and future demands of obstetric and general hospitals.

All requests for information and for material should be addressed to the Blood Grouping Laboratory, 300 Avenue, Boston 15, Massachusetts.
